- Although respiratory failure is the most common cause of death, other causes may contribute including hypoxia due to seizures, hyperthermia, renal failure, and hepatic failure. Nephrotoxicity has been postulated to be a matter of concern in some cases of organophosphate poisoning which is often not paid due attention by the attending physician.
- Unequal sympathetic stimulation of myocardial cells and interactions with potassium channels and the Na^+/Ca^{++} exchanger in the myocardial cell membrane are probably responsible for the occasional prolonged QTc interval. This prolongation in QTc interval can be associated with polymorphic ventricular tachycardia (torsades de pointes). Finally, hypotension may occur because of stimulation of vascular receptors by excessive circulating ACh. Patients with OP poisoning and QTc prolongation are more likely to develop respiratory failure and have a worse prognosis than patients with normal QTc intervals. Patients with OP poisoning who develop premature ventricular contractions (PVCs) are more likely to develop respiratory failure and have a higher mortality rate than patients without PVCs.
- Because liquid preparations are usually dissolved in a hydrocarbon, aspiration frequently results following ingestion in severe poisoning and can lead to hydrocarbon pneumonitis.
- Excessive adrenergic influences on metabolism cause glycogenolysis with hyperglycemia and ketosis that may be mistaken for diabetic ketoacidosis. Hypoglycemia can also occur, although the mechanism is unclear. Increased sympathetic activity usually precipitates white blood cell demargination, resulting in leukocytosis.
- Elevations of hepatic enzymes can occur following OP pesticide exposures.

Intermediate Syndrome

- An intermediate syndrome sometimes occurs 1–4 days after poisoning due to long-lasting cholinesterase inhibition and muscle necrosis. This phenomenon was first described in 1987 and is termed the "intermediate syndrome" because it occurs in between the periods of acute and delayed toxicity. It is more common with chlorpyriphos, dimethoate, monocrotophos, parathion, sumithion, fenthion, fenitrothion, ethyl parathion, methyl parathion, diazinon, malathion, trichlorfon, and methamidophos. Redistribution of these lipophilic pesticides and their metabolites from adipose tissue may be responsible, and the syndrome may resolve when the body burden of these metabolites diminishes and cholinesterase levels normalize. The main features include muscle weakness and paralysis. The most commonly affected muscles are the facial, extraocular, palatal, respiratory, and proximal limb muscles. Paralytic signs include inability to lift the neck or sit up, ophthalmoparesis, slow eye movements, facial weakness, difficulty swallowing, limb weakness (primarily proximal), areflexia, respiratory paralysis, and death. There is growing speculation that intermediate syndrome may result from inadequate oxime therapy, although more recent case reports question this theory. One recent study suggests that the occurrence of intermediate syndrome strongly correlates with the initial degree of cholinergic crisis and appears to be a continuum with the neuromuscular paralysis resulting from the early stages of

poisoning. The study suggests that muscle injury during early cholinergic crisis may progress to intermediate syndrome. Electromyograms will often show tetanic fade in these patients and suggest both pre- and postsynaptic involvement. However, repetitive nerve stimulation may not always accurately predict the occurrence or severity of intermediate syndrome but may be beneficial in determining the need for mechanical ventilation. Once it sets in, the intermediate syndrome will have to be managed by supportive measures, since it does not respond to oximes or atropine. However, because some reports correlating pralidoxime dose and intermediate syndrome suggest that insufficient dosing may play a part, it is recommended that pralidoxime infusion be reinstituted at 500 mg/h when intermediate syndrome is suspected. The weakness and paralysis commonly resolve in 5–18 days. In one study from India, up to one third of admissions of organophosphate poisoning in a major hospital developed intermediate syndrome.

- A delayed syndrome (now called delayed encephalopathy and neuropathy syndrome) sometimes occurs 1–4 weeks after poisoning due to nerve demyelination and is characterized by flaccid weakness and atrophy of distal limb muscles or spasticity and ataxia. A mixed sensory-motor neuropathy usually begins in the legs, causing burning or tingling, then weakness. Severe cases progress to complete paralysis, impaired respiration, and death. The nerve damage of organophosphate-induced delayed neuropathy is frequently permanent. This disorder seems to result from inhibition of an enzyme within nervous tissue named neurotoxic esterase or NTE. Symptoms seem to be initiated by the phosphorylation of this enzyme, or perhaps of some related compound, followed by the aging of the complex. Such neuropathies may even result from exposure to OP compounds that do not inhibit red blood cell (RBC) cholinesterase or produce clinical cholinergic toxicity. Pathologic findings demonstrate effects primarily on large distal neurons, with axonal degeneration preceding demyelination. Organophosphates that have been associated with delayed neuropathy in humans include chlorophos, chlorpyriphos, dichlorvos, dipterex, ethyl parathion, fenthion, isofenphos, leptophos, malathion, mecarbam, mephosfolan, merphos, methamidophos, mipafox, trichlorfon, trichloronate, and TOCP. Electromyograms and nerve conduction studies may be helpful in diagnosing the delayed syndrome by identifying the type of neuropathy (such as axonopathy, myelinopathy, or transmission neuropathy) and differentiating it from similar presentations such as Guillain–Barré syndrome. Recovery of these patients is variable and occurs over months to years, with residual deficits common.
- Hyperamylasemia is occasionally reported in cases of severe OP pesticide poisoning, and although pancreatitis may result from spasm of the sphincter of Oddi, hyperamylasemia is most often the result of salivary gland stimulation and not the result of pancreatic dysfunction. Parathion ingestion has resulted in fatal hemorrhagic pancreatitis. Diazinon has also been implicated. Hemoperfusion is said to be beneficial if this occurs.
- Patients poisoned with highly lipid-soluble Ops, such as fenthion, have rarely developed extrapyramidal effects including dystonia, resting tremor, cog-wheel rigidity, and choreoathetosis. These effects began 4–40 days after acute OP poisoning and spontaneously resolved over 1–4 weeks in survivors.
- It is important to note that children may have different predominant signs of organophosphate poisoning than adults. In some studies of children poisoned by organophosphate or carbamate compounds, the major signs and symptoms were CNS depression, stupor, flaccidity, dyspnea, and coma. Other classical signs of organophosphate poisoning such as miosis, fasciculations, bradycardia, excessive salivation and lacrimation, and GI symptoms were infrequent.

Chronic Organophosphates Poisoning

It usually occurs as an occupational hazard in agriculturists, especially those who are engaged in pesticide spraying of crops. The route of exposure is usually inhalation or contamination of the skin. Following are the main features:

- *Polyneuropathy*: Paresthesias, muscle cramps, weakness, gait disorders
- *CNS effects*: Drowsiness, confusion, irritability, anxiety
- *Sheep farmer's disease*: Psychiatric manifestations encountered in sheep farmers involved in long-term sheep-dip operations.
- A study of 24 agricultural workers revealed significantly lower cancellous bone area and bone formation at cellular and tissue levels in workers with long-term exposure to organophosphates compared with healthy age-matched controls.
- Organophosphate poisoning has been associated with a variety of subacute or delayed onset chronic neurological, neurobehavioral, or psychiatric syndromes. One author has termed these "chronic organophosphate induced neuropsychiatric disorder (COPIND)" and noted that the standard hen neurotoxic esterase test is not sufficient to detect which OPs can cause this condition. Signs and symptoms include confusion, psychosis, anxiety, drowsiness, depression, fatigue, and irritability. Electroencephalographic changes may be noted and can last for weeks. Single-photon emission computed tomography (SPECT) scanning may reveal morphologic changes in the basal ganglia. Although no specific treatment is effective, most psychological abnormalities resolve within a year.
- A cluster of congenital anomalies has been reported in a Hungarian village where pregnant women were believed to have consumed trichlorfon-contaminated fish during pregnancy. Of 15 live births, 11 (73%) had congenital abnormalities and 6 were twins. Other likely causes (known teratogenic factors, familial inheritance, consanguinity) were excluded. Abnormalities included Down syndrome (4 births), ventricular septal defect and pulmonary atresia, congenital inguinal hernia, stenosis of the left bronchus, anal atresia, choanal atresia, cleft lip, and Robin sequence.
- In a pesticide exposure study in children, a significant association was found between the risk of non-Hodgkin lymphoma and increased frequency of reported pesticide use in the home, professional exterminations within the home, and postnatal exposure. Higher risks were found in both young (younger than 6 years of age) and older children, for T-cell and B-cell lymphomas and for lymphoblastic large cell Burkitt's lymphoma. In addition,

there was a higher risk for non-Hodgkin lymphoma with occupational exposure to pesticides.

- Some studies indicate a link between Parkinson disease and chronic exposure to OP insecticides. The structures of some of these compounds are similar to those of known neurotoxins like 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Some individuals may have a possible genetic susceptibility. In some cases of acute exposure to OP compounds, there have been reports of self-limited movement disorders resembling Parkinson that resolve over weeks to months. Although statistics derived from some epidemiologic studies suggest the connection, other studies have failed to find an association between OP compounds and Parkinsonism.

There are some organophosphates that are extremely potent but do not find a place as insecticides; instead, they have been used in chemical warfare. These include sarin, tabun, soman, etc.

Diagnosis

Depression of Cholinesterase Activity

Plasma cholinesterase (butyrylcholinesterase) metabolizes various xenobiotics, including succinylcholine and cocaine. Erythrocytes contain a form of AChE (RBC cholinesterase) that is structurally similar to the enzyme found in neuronal tissue. Inhibition of either RBC cholinesterase or plasma cholinesterase serves as marker for cholinesterase inhibitor poisoning, but the extent of inhibition of these enzymes does not correlate well with the severity of poisoning. There is also tremendous interindividual and interchemical variability in the degree and duration with which OP insecticides affect various cholinesterases.

After significant exposure, plasma cholinesterase activity usually falls first, followed rapidly by RBC cholinesterase. By the time patients present with acute symptoms, the levels of both cholinesterase activities have usually fallen well below baseline values and often have fallen below detectable limits. Plasma cholinesterase activity usually recovers before RBC cholinesterase activity, often returning to normal within a few days. However, plasma cholinesterase activity is less specific for exposure than is RBC cholinesterase activity. The former can be lowered significantly in patients with a number of disorders, including hereditary deficiency of the enzyme, malnutrition, hepatic parenchymal disease, chronic debilitating illnesses, and iron deficiency anemia. In fact, day-to-day variation in the activity of this enzyme in healthy individuals may be as high as 20%.

Red blood cell cholinesterase activity is more reliable because the AChE in RBCs is true AChE. It is generally suggested that clinical OP pesticide poisoning can be said to have occurred when RBC cholinesterase activity falls to below 50% of baseline values.

However, there are several pitfalls in interpreting cholinesterase laboratory values. First, it is AChE inhibition in nervous tissue that causes toxicity, and RBC and plasma cholinesterase activity may not always reflect neuronal enzyme activity. OP insecticides vary in their ability to inhibit both enzymes. Because these tests are only markers of neuronal enzyme inhibition, this variation may lead to some patients presenting highly symptomatic after minimal reductions in RBC or plasma cholinesterase, although others can be asymptomatic after losing 50% activity. It is also well known that there is a wide normal range of RBC and plasma cholinesterase activity, which allows for patients with high normal values to suffer significant falls in cholinesterase activity, yet still register near-normal levels of cholinesterase activity on laboratory assay.

Red blood cell cholinesterase regenerates more slowly than AChE found in neurons. To completely replenish the RBC AChE supply, the RBCs in circulation at the time of the OP insecticide exposure must be replaced or pralidoxime administered. An average of 66 days may be necessary for RBC cholinesterase activity to recover following severe inhibition, and activity may take up to 120 days to return to normal. The patient may have completely recovered neuronal activity of AChE and resolved all cholinergic symptoms, yet still has low RBC cholinesterase laboratory values. For this reason, in subacute poisoning with OP compounds, it is difficult to accurately predict the actual time of onset or duration of exposure when only the RBC cholinesterase activity is known. In fact, the ability of RBC cholinesterase activity to serve as a historical marker for excessive exposure to OP insecticides provides the basis for monitoring the activity of this enzyme in pesticide workers.

It is important to note that depressed RBC cholinesterase activity may be the result of exposures or conditions other than insecticide poisoning, such as in therapy with antimalarial agents such as chloroquine and pernicious anemia. Genetic and circadian variations are also common, with daily fluctuations within the same individual as high as 10%. Additionally, levels are normally slightly lower in children younger than 4 months of age, probably increasing as hepatic function matures. Oral contraceptives raise RBC cholinesterase activity.

Blood samples for cholinesterase activity must be obtained in the appropriate blood tubes. Tubes containing fluoride will permanently inactivate the enzyme, yielding falsely low activity levels, and should not be used. Specimens for RBC cholinesterase must be drawn into tubes containing a chelating anticoagulant such as ethylenediaminetetraacetic acid (EDTA) to prevent clot formation. Plasma cholinesterase does not require an anticoagulant and can be drawn into a tube without chelators or anticoagulants.

Table 3 gives an overview of the benefits and disadvantages of estimating RBC and plasma cholinesterase levels in suspected OP or carbamate pesticide poisoning.

Plasma cholinesterase usually recovers in a few days or weeks; RBC cholinesterase recovers in several days to 4 months depending on the severity of depression. Some studies have found plasma cholinesterase either to have no significant association with the mortality or as a means to assess the need for patients requiring ventilator support.

P-nitrophenol Test

P-nitrophenol is a metabolite of some organophosphates (e.g., parathion, ethion) and is excreted in the urine.

Procedure of the test: Steam distills 10 mL of urine and collect the distillate. Add sodium hydroxide (2 pellets) and heat on a water bath for 10 minutes. Production of yellow color indicates the presence of p-nitrophenol. The test can also be done on vomitus or stomach contents.

Levels of alkyl phosphates, such as diethylphosphate (DEP) and dimethylphosphate (DMP), may be more sensitive markers of exposure.

TABLE 3: Comparison of RBC and plasma cholinesterase assays in OP/carbamate poisoning.		
	RBC cholinesterase	***Plasma cholinesterase***
Advantage	More reliable	Easier to measure, declines faster
Site	RBC (reflects CNS grey matter, motor endplate)	CNS white matter, plasma, liver, pancreas, heart
Regeneration (untreated)	1%/day	25–30% in first 7–10 days
Normalization (untreated)	35–49 days	28–42 days
Use	Unsuspected prior exposure with normal plasma cholinesterase	Acute exposure
False depression	Pernicious anemia, hemoglobinopathies, antimalarial treatment, oxalate blood tubes	Liver dysfunction, malnutrition, hypersensitivity reactions, drugs (succinylcholine, codeine, morphine), pregnancy, genetic deficiency

(CNS: central nervous system; RBC: red blood cell)

Atropine Challenge Test

An atropine sulfate challenge may be helpful in diagnosing cholinergic poisoning in a patient who presents with findings suggestive of this disorder, but in whom no history is available to suggest excessive exposure to an OP or carbamate insecticide. In an individual not exposed to significant amounts of insecticide, a test dose of 1–5 mg of atropine (adult), or 0.05 mg/kg (children), should produce classic antimuscarinic findings such as mydriasis, tachycardia, and dry mucous membranes. Conversely, the persistence of cholinergic signs and symptoms after an atropine challenge strongly suggests the presence of OP compound or carbamate poisoning. However, some patients suffering from mild-to-moderate anticholinesterase poisoning may respond to these doses of atropine. Therefore, the reversal of cholinergic findings does not exclude poisoning by one of these compounds.

Electromyogram

Repetitive nerve stimulation testing is an accurate method of quantifying AChE inhibition at the neuromuscular junction. Spontaneous repetitive potentials or fasciculations following single-nerve stimulation resulting from persistent ACh at nerve terminals can be a sensitive indicator of AChE inhibition at the motor endplate and may be useful in the early diagnosis of OP or carbamate poisoning. This kind of evaluation may also be of benefit in early detection of rebound cholinergic crisis caused by continued insecticide absorption or redistribution from adipose tissue, or onset of an intermediate syndrome.

Thin Layer Chromatography

The presence of an organophosphate in a lavage, or vomit, or gastric aspirate sample can also be determined by thin layer chromatography (TLC). The sample is extracted twice with 5 mL of petroleum ether, and the extract is washed with distilled water. It is then dried in steam-compressed air, reconstituted in methanol, and spotted on silica gel-coated TLC plate along with the standard and run in a mixture of petroleum ether and methanol (25:1). After the solvent has traveled a considerable distance, the plate is dried and exposed to iodine vapor. The RF is compared with that of the standard.

Ancillary Investigations

There may be evidence of:

- Leukocytosis (with relatively normal differential count)
- High hematocrit
- Anion gap acidosis
- Hyper- or hypoglycemia. Hypoglycemia can be recalcitrant to treatment.
- Elevation of serum creatine kinase

In every case, monitor electrolytes, ECG, and serum pancreatic isoamylase levels in patients with significant poisoning. Patients who have increased serum amylase levels and those who develop a prolonged QTc interval or PVCs are more likely to develop respiratory insufficiency and have a worse prognosis. If pancreatitis is suspected, an abdominal CT-scan can be performed to evaluate diffuse pancreatic swelling. If respiratory tract irritation is present, monitor chest X-ray. Many organophosphate compounds are found in solution with a variety of hydrocarbon-based solvents. Aspiration pneumonitis may occur if these products are aspirated into the lungs. Bronchopneumonia may develop as a complication of organophosphate-induced pulmonary edema. High-performance thin layer chromatography (HPLC) technique can be used to identify several organophosphate compounds in human serum.

Treatment

Determine plasma or RBC cholinesterase activities. Depression in excess of 50% of the baseline is generally associated with severe symptoms (*vide supra*). The initial treatment for a patient exposed to OP compounds must be directed at ensuring an adequate airway and ventilation and at reversing excessive muscarinic effects. Seizures must be treated with standard anticonvulsants such as benzodiazepines or barbiturates.

Decontamination

- If skin spillage has occurred, it is imperative that the patient be stripped and washed thoroughly with soap and water.
  Procedure:
  - Shower is preferable. Make the patient stand (if he/she is able to) under the shower or seated in a chair.
  - Wash with cold water for 5 minutes from head to toe using nongermicidal soap. Rinse hair well.
  - Repeat the wash and rinse procedure with warm water.
  - Repeat the wash and rinse procedure with hot water.

  Treating personnel should protect themselves with water-impermeable gowns, masks with eye shields, and shoe covers. Neoprene or nitrile gloves must be used, if available. Double-gloving with standard vinyl gloves may be protective for short intervals. Although alcohol-based soaps are sometimes

recommended to dissolve hydrocarbons, these products can be difficult to find, and immediate skin cleansing should be the primary goal. It must be noted that skin absorption can also result from contact with OP compounds in vomitus and diarrhea. Oily insecticides may be difficult to remove from thick or long hair, even with repeated shampooing, and shaving scalp hair may be necessary. Exposed leather clothing or products should be discarded because decontamination is very difficult once impregnation has occurred.

- If ocular exposure has occurred, copious eye irrigation should be done with normal saline or Ringer's solution. If these are not immediately available, tap water can be used.
- In the case of ingestion, stomach wash can be done, though this is often unnecessary because the patient would have usually vomited by the time he is brought to the hospital. Activated charcoal can be administered in the usual way even though the evidence is lacking as to its efficacy in OP poisoning. One dose (1 g/kg) may be sufficient.

Decontamination of Spills

A variety of methods have been described for organophosphate spill decontamination, most of which depend on changing the pH to promote hydrolysis to inactive phosphate diester compounds. The rate of hydrolysis depends on both the specific organophosphate compound involved and the increase in pH caused by the detoxicant used.

- Caution! Do not use a mixture of bleach and alkali for decontaminating acephate organophosphates. This can cause release of toxic acetyl chloride, acetylene, and phosgene gas. Spills of acephate organophosphates should be decontaminated by absorption and scrubbing with concentrated detergent.
- Treatment of the spilled material with alkaline substances such as sodium carbonate (washing soda), sodium bicarbonate (baking soda), calcium hydroxide (slaked or hydrated lime, or lime water), and calcium carbonate (limestone) may be used for detoxification.
- Chlorine-active compounds such as sodium hypochlorite (household bleach) or calcium hypochlorite (bleaching powder, chlorinated lime) may also be used to detoxify organophosphate spills.
- Disposal of large quantities or contamination of large areas may be regulated by various governmental agencies and reporting may be required.

Antidotes

- *Atropine*: Atropine, a competitive antagonist of acetylcholine at the muscarinic postsynaptic membrane and in the CNS, will block the muscarinic manifestations of organophosphate poisoning.
- *Pralidoxime*: This is a nucleophilic oxime which helps to regenerate AChE at muscarinic, nicotinic, and CNS sites. Actually, human studies have not substantiated the benefit of oxime therapy in acute organophosphate poisoning, but they are widely used. Most authors advocate the continued use of pralidoxime in the clinical setting of severe organophosphate poisoning. The antidotes for organophosphates have been discussed in details further in this chapter.

Supportive Measures

Maintain airway patency and oxygenation. Suction secretions. Endotracheal intubation and mechanical ventilation may be necessary. Monitor pulse oximetry or arterial blood gases to determine the need for supplemental oxygen.

- Administer intravenous (IV) fluids to replace losses.
- Oxygenation/intubation/positive pressure ventilation. To minimize barotrauma and other complications, use the lowest amount of positive end-expiratory pressure (PEEP) possible while maintaining adequate oxygenation. Use of smaller tidal volumes (6 mL/kg) and lower plateau pressures (30-cm water or less) has been associated with decreased mortality and more rapid weaning from mechanical ventilation in patients with ARDS.
- The following drugs are contraindicated: Parasympathomimetics, phenothiazines, antihistamines, and opiates. Do not administer succinylcholine (suxamethonium) or other cholinergic medications. Prolonged neuromuscular blockade may result when succinylcholine is administered after organophosphate exposure.
- Treat convulsions with benzodiazepines or barbiturates.
- Antibiotics are indicated only when there is evidence of infection.
- Hemoperfusion, hemodialysis, and exchange transfusion have not been shown to affect the outcome or duration of toxicity in controlled trials of organophosphate poisoning.

Prevention of Further Exposure

After the patient has recovered, he/she should not be re-exposed to organophosphates for at least a few weeks since he/she is likely to suffer serious harm from a dose that normally would be harmless, owing to the alteration of body chemistry.

Following acute poisoning, patients should be precluded from further organophosphate exposure until sequential RBC cholinesterase (AChE) levels have been obtained and confirm that AChE activity has reached a plateau. Plateau has been obtained when sequential determinations differ by number >10%. This may take 3–4 months following severe poisoning.

Treatment of a Pregnant Victim

Therapeutic choices during pregnancy depend upon specific circumstances such as stage of gestation, severity of poisoning, and clinical signs of mother and fetus. The mother must be treated adequately to treat the fetus. A severely poisoned patient with a late gestation viable fetus may be a candidate for an emergency cesarean section. The fetus may require intensive care after birth. Pralidoxime chloride is recommended for use in the pregnant patient to counteract muscle weakness. Both atropine and pralidoxime are pregnancy class C drugs and therefore not contraindicated outright.

Glycopyrrolate: Unlike atropine, glycopyrrolate usually does not readily cross the placenta and would not directly affect fetal poisoning. However, the fetus may be best served by treating the mother to retain good respiratory function and fetal oxygenation.

Autopsy Features

External:

- Characteristic odor (garlicky or kerosene-like)
- Frothing at mouth and nose. Some compounds may impart a characteristic discoloration, e.g., greenish in dichlorvos poisoning (**Fig. 3**).
- Cyanosis of extremities
- Constricted pupils

FIG. 3: Greenish frothy fluid oozing out of mouth and nose—dichlorvos poisoning. ***(For color version, see plate 37)***

Courtesy: Dr Swapnil Agarwal.

Internal:

- Congestion of GI tract; garlicky or kerosene-like odor of contents
- Pulmonary and cerebral edema
- Generalized visceral congestion

A useful sign in mortuaries infested with flies is that some of these flies after settling on an opened body (dead of organophosphate poisoning) may themselves subsequently die and land on the autopsy table. It is also pertinent to remember that organophosphates resist autolysis and can be easily detected even in putrefied bodies.

Antidotes for Organophosphates

Atropine

Mode of action: It blocks the muscarinic manifestations of organophosphates. However, since atropine affects only the postsynaptic muscarinic receptors, it has no effect on muscle weakness or paralysis.

Diagnostic dose: Organophosphate-poisoned patients are generally tolerant to the toxic effects of atropine (dry mouth, rapid pulse, dilated pupils, etc.). If these findings occur following a diagnostic atropine dose, the patient is probably not seriously poisoned.

Diagnostic dose: Adult: 1 mg intravenously or intramuscularly; Child: 0.25 mg (about 0.01 mg/kg) intravenously or intramuscularly

Therapeutic dose: 1–2 mg IV or IM (*adult*); 0.05 mg/kg IV (*child*); every 15 minutes until the endpoint is reached, i.e., drying up of tracheobronchial secretions. Pupillary dilatation and tachycardia are not reliable indicators of the endpoint. Atropine can also be administered as an IV infusion after the initial bolus dose, at a rate of 0.02–0.08 mg/kg/h. Once the endpoint has been reached, the dose should be adjusted to maintain the effect for at least 24 hours. Atropinization must be maintained until all of the absorbed organophosphate has been metabolized. This may require administration of 2–2,000 mg of atropine over several hours to weeks. Large doses of atropine are often needed to reverse the bronchospasm, bronchorrhea, bradycardia, and heart block associated with severe OP pesticide toxicity. Some patients with mild symptoms need only 1 or 2 mg of atropine to reverse cholinergic toxicity, but the moderately poisoned adult commonly requires total doses as large as 40 mg or more. Severe poisonings may necessitate even higher doses. Some adults have received over 1,000 mg of atropine in 24 hours (with adequate pralidoxime dosing) without demonstrating antimuscarinic effects, and total doses as high as 11,000 mg during the course of treatment have been reported. Children have been managed with continuous infusions of atropine starting at 0.025 mg/kg/h, and adult infusions of atropine can begin at 0.5–1 mg/h and titrated as needed. Continuous infusions have been used for as long as 32 days in severely poisoned patients.

Atropine therapy must be withdrawn slowly to prevent recurrence or rebounding of symptoms, often in the form of pulmonary edema. This is especially true of poisonings from lipophilic organophosphates such as fenthion.

Precautions:

- Many parenteral atropine preparations contain benzyl alcohol or chlorobutanol as preservatives. High-dose therapy with these preparations may result in benzyl alcohol or chlorobutanol toxicity. Preservative-free atropine preparations are available and should be used if large doses are required.
- The half-life of atropine is significantly longer in children under 2 years and adults over 60 years; the rate of administration in these patients should be adjusted accordingly.
- Effects of overdosing with atropine include fever, warm dry skin, inspiratory stridor, irritability, and dilated and unresponsive pupils.
- A urinary catheter should be inserted in all atropinized patients to prevent urinary retention.
- If atropine supplies are exhausted during therapy, other antimuscarinic agents like diphenhydramine may be used.

Endpoint: "Atropinization" is said to have occurred when the patient exhibits dry skin and mucous membranes, decreased or absent bowel sounds, tachycardia, reduced secretions, no bronchospasm, and mydriasis. Reduction or disappearance of pulmonary secretions is the most important target in atropine therapy and can be guided by following lung sounds and oxygenation. Tachycardia is not a contraindication to atropine therapy. Although the pupils are often helpful in gauging the need for atropine, the miosis encountered in severe ingestions and by direct ocular exposure to OP insecticides may respond only to topical ophthalmic atropine. Conversely, a positive pupillary response alone should not be used to discontinue further therapy.

Adverse effects: Atrial arrhythmias, A-V dissociation, multiple ventricular ectopics, photophobia, raised intraocular pressure, hyperpyrexia, hallucinations, and delirium

Glycopyrrolate

When antimuscarinic CNS toxicity becomes evident, yet peripheral cholinergic findings necessitate the administration of more atropine (e.g., bradycardia, bronchorrhea, vomiting), glycopyrrolate bromide can be substituted for atropine because its quaternary ammonium structure limits CNS penetration.

The initial IV dose of glycopyrrolate for adults is 1–2 mg, repeated as needed, and in children 0.025 mg/kg up to adult doses. As with atropine, much higher doses of glycopyrrolate may be required to stabilize patients with severe poisoning.

Pralidoxime: PAM (Pyridine-2-aldoxime Methiodide)

Structurally, pralidoxime is 2-hydroxyiminomethyl-1-methylpyridinium chloride.

Mode of action: It is usually given along with atropine. Although phosphorylated AChE undergoes hydrolytic regeneration at a very slow rate, this process can be markedly enhanced by using an oxime such as pralidoxime hydrochloride (2-PAM). In addition to rejuvenating AChE, pralidoxime may also reverse toxicity by directly inactivating free OP molecules and by exhibiting an apparent antimuscarinic effect on nervous tissue. Regeneration of AChE lowers ACh concentrations to normal levels, reversing both muscarinic and nicotinic effects. An immediate rise in RBC cholinesterase activity is often noted after the administration of pralidoxime.

Pralidoxime competes for the phosphate moiety of the OP compound and releases it from the AChE enzyme, thereby liberating the latter and reactivating it. Most phosphorylated AChE will usually be "aged" within 24–48 hours of exposure. Pralidoxime is unable to rejuvenate active enzyme from the OP compound-AChE complex that has undergone aging. Therefore, pralidoxime therapy is most effective if started early in the course of toxicity. The actual rate of aging, however, varies significantly among OP compounds. Although it is advisable to begin pralidoxime therapy within 48 hours of poisoning, it can be administered even much later with beneficial effects. Circulating OP pesticide concentrations have been measured for as long as 48 days after exposure, either because of prolonged absorption from the GI tract or because of redistribution from fat stores. Therefore, some AChE may still be undergoing new inhibition for days or weeks after exposure in symptomatic patients, and such inhibition may be reversible by pralidoxime. Some reports support this theory by recording dramatic effects in reversing paralysis, weakness, and cholinergic symptoms even after late administration of pralidoxime.

Pralidoxime is not equally effective in reversing cholinergic symptoms in all types of OP compound poisonings. It is particularly effective in reversing toxicity from parathion, diazinon, methyl parathion, TEPP, dimethoate, and dichlorvos but dimethoxy compounds, such as malathion and methyl demeton, may be more resistant to reversal.

Till recently, pralidoxime was said to be contraindicated in carbamate poisoning because experiments with carbaryl (*Sevin*) suggested a worsening of symptoms when it was administered. However, studies have pointed out that while pralidoxime is not a necessary adjunct to atropine in carbamate overdose, it may be beneficial in some cases.

Dose: *For adults*: 1–2 g in 100–150 mL of 0.9% sodium chloride, given IV over 30 minutes. This can be repeated after 1 hour, and subsequently every 6–12 hours, for 24–48 hours. Alternatively, a 2.5% concentration of pralidoxime can be given as a loading dose followed by a maintenance dose. Serious intoxication may require continuous infusion of 500 mg/h in adults. Many workers feel that this high-dose therapy minimizes the incidence of complications such as the intermediate syndrome. Maximum dose should not exceed 12 g in a 24-hour period. Infusion over a period of several days may be necessary and is generally well tolerated. Although minimal serum concentrations of 4 μg/mL are estimated to be necessary for the maintenance of enzyme reactivation, the degree of reactivation may be dependent on the specific identity and concentrations of both oxime and OP compound. Bolus dosing of pralidoxime every 4–8 hours is ineffective in maintaining these levels, and therefore a constant infusion appears to be more appropriate. Present recommendations for adults are to begin the maintenance infusion at 250–500 mg/h, titrating to symptoms. Alternative dosing by weight reported in other studies suggests using 4–5 mg/kg as a loading dose over 15–30 minutes, followed by a continuous infusion of 2–4 mg/kg/h to maintain serum concentrations.

The World Health Organization (WHO) currently recommends an initial bolus of at least 30 mg/kg, followed by an infusion of >8 mg/kg/h.

For children: About 20–40 mg/kg to a maximum of 1 g/dose given IV and repeated every 6–12 hours for 24–48 hours. Alternatively, IV infusion can be resorted at a rate of 9–19 mg/kg/h.

Adverse effects: Side effects of pralidoxime are usually minimal at normal doses. Severely poisoned patients have received 500 mg/h for weeks without adverse effects. Rapid infusion can cause mild cholinergic effects because of transient blockade of AChE and has resulted in neuromuscular blockade and central respiratory depression. Occasional visual complaints are also reported in patients receiving pralidoxime. Rapid administration can cause tachycardia, laryngospasm, and even cardiac or respiratory arrest. Other adverse effects include drowsiness, vertigo, headache, and muscle weakness.

It is generally not advised for the treatment of carbamate overdose, especially carbaryl.

In cases where IV administration is not possible, pralidoxime can be given intramuscularly as an initial dose of 1 g or up to 2 g in cases of very severe poisoning. Recent research in animals suggests that oral dosing of pralidoxime and atropine may also improve survival.

In some countries, obidoxime is used instead of pralidoxime, although it does not appear to be superior to the latter. It is apparently favored over pralidoxime in clinical practice in Belgium, Israel, The Netherlands, Scandinavia, and Germany and is the only oxime available in Portugal.

Several investigators have started suggesting that oximes have only a limited role in organophosphate poisoning, and successful management is possible without employing them at all, though this view is not shared by some other workers in the field.

Diazepam

Several studies demonstrate that administering diazepam along with oximes in the treatment of OP nerve agents (sarin, soman, tabun, VX) or OP pesticides can increase survival and decrease the incidence of seizures and neuropathy. Diazepam can also decrease cerebral morphologic damage resulting from OP compound-induced seizures. Some investigators suggest that diazepam may also help attenuate OP-induced respiratory depression by minimizing the overstimulation of central respiratory centers caused by OP insecticides.

Dose: *For adults*: 5–10 mg IV slowly, every 15 minutes, up to a maximum of 30 mg.

For children: 0.25–0.4 mg/kg IV slowly, every 5–10 minutes, up to a maximum of 10 mg.

If diazepam is ineffective, phenytoin or phenobarbitone can be used instead.

CARBAMATES

Carbamates are as popular as organophosphates in their role as insecticides (and fungicides) and share a number of similarities. Only the differentiating features will be discussed. Indian brands are listed in **Table 4**.

Usual Fatal Dose

The following are *extremely toxic* (*LD50*: *1–50 mg/kg*) or highly toxic (*LD50*: *51–500 mg/kg*): Aminocarb, Bendiocarb, Benfuracarb, Carbaryl, Carbofuran, Dimetan, Dimetilan, Dioxacarb, Formetanate, Methiocarb, Methomyl, Oxamyl, Propoxur.

The following are *moderately toxic* (*LD50*: *501–5,000 mg/kg*) or slightly toxic (*LD50*: *>5,000 mg/kg*): Aldicarb, Bufencarb, Isoprocarb, MPMC, MTMC, Pirimicarb.

Mode of Action and Clinical Features

Carbamates were discovered in the 19th century when it was observed that the calabar bean (*Physostigma venenosum Balfour*) (**Fig. 4**) was being used in tribal rituals in West Africa. These beans were imported to Great Britain in 1840, wherein 1864, Jobst and Hesse isolated an active alkaloid they named "physostigmine." This alkaloid was first medicinally used to treat glaucoma in 1877. In the 1930s, the synthesis of aliphatic esters of carbamic acid led to the development and introduction of carbamate pesticides, marketed initially as fungicides. In 1953, the Union Carbide Corporation developed and first marketed carbaryl, the very same insecticide that was being manufactured at the notorious plant in Bhopal, during the methyl isocyanate tragedy in 1984.

TABLE 4: Common carbamates.

Generic name	*Brand name*
Aldicarb	Aldrin, Temik
Carbaryl	Agrovin, Agroyl, Bangvin 50, Caravet, Corovin, Hexavin, Kevin 50, Kilex Carbaryl, Sevidal, Sevin 50, Sujacarb, Sulfarl 50
Carbaryl + Gamma BHC	Sevidol
Carbofuran	Agrofuron 3G, Carbocil 3, Carburan, Crane, Furadan 3G, Hexafuran, VegFru Diafuran
Carbosulfan	Marshal
Fenobucarb	Merlino
Methomyl	Astra, Dunet, Lannate, Lannet, Mathoyl
MPMC (Xylylcarb)	Bipuin
MTMC (Metolcarb)	Emisan
Propoxur	Baygon, Isocarb, Protox Bait
Thiodicarb	Larvin

As described in the previous chapter, those cholinesterase-inhibiting (anticholinesterase) insecticides that contain phosphorus are collectively termed OP compounds, while those that contain the OC=ON linkage are termed carbamates. Most carbamate insecticides are N-methyl carbamates derived from carbamic acid. Medicinal carbamate compounds include physostigmine, pyridostigmine, and neostigmine. Drugs such as meprobamate and various urethanes are also carbamate derivatives, but they do not inhibit cholinesterase. Thiocarbamate fungicides and herbicides (e.g., maneb, zineb, nabam, mancozeb) also do not inhibit AChE and do not produce cholinergic excess.

Carbamates (like organophosphates) are inhibitors of AChE, but carbamylate the serine moiety at the active site instead of phosphorylation. This is a reversible type of binding and hence symptoms are less severe and of shorter duration. Aging cannot occur since the carbamate-AChE bond hydrolyzes spontaneously, reactivating the enzyme. As such, the duration of symptoms in carbamate poisoning is generally <24 hours. As a result, both morbidity and mortality are limited when compared to organophosphate poisoning. Also, since carbamates do not penetrate the CNS to the same extent as organophosphates, CNS toxicity is likewise much less. With respect to all other clinical manifestations, there is a general similarity between carbamates and organophosphates.

Carbamates are well absorbed across skin and mucous membranes, and by inhalation and ingestion. Peak serum levels of some compounds are generally achieved in 30–40 minutes following ingestion. Most carbamates undergo hydrolysis, hydroxylation, and conjugation in the liver and intestinal wall, with 90% excreted in the urine within 3 days. There are two main pharmacokinetic differences between carbamates and OP compounds. First, carbamates do not easily cross into the CNS. CNS effects are thus limited, although CNS dysfunction may still occur in massive ingestion (especially aldicarb), or from hypoxia secondary to pulmonary toxicity and paralysis. Second, the carbamate-cholinesterase bond does not "age" as in OP compound poisoning; thus it is reversible, with spontaneous hydrolysis occurring usually within several hours. Carbamates are rapidly metabolized. Most of them are rapidly hydrolyzed by liver enzymes to methyl carbamic acid and a

FIG. 4: *Physostigma venenosum*—calabar bean. ***(For color version, see plate 37)***

variety of low toxicity phenolic substances. These metabolites may sometimes be measured in urine as long as 2–3 days after significant pesticide absorption.

Miosis, a muscarinic effect, is characteristic of severe and moderately severe poisonings, but may appear late.Miosis was the most common symptom seen (57%) in a retrospective observational study of 54 children admitted to a pediatric intensive care unit following anticholinesterase (carbamate and organophosphate) poisoning. Pupil dilation may occur as a nicotinic effect and may be present in up to 10% of patients.

Sinus tachycardia with ST segment depression may occur early in the course of poisoning. Repolarization abnormalities may occur and are generally transient. Complete heart block has been reported.

Dyspnea is a common manifestation of carbamate exposure. Chest tightness, bronchospasm, increased pulmonary secretions, and rales may develop secondary to muscarinic effects. Acute lung injury (pulmonary edema) is a potential clinical manifestation of severe carbamate poisoning and is attributed to the muscarinic action of the insecticide. Contributing factors to the development of pulmonary edema include bradycardia and weakened cardiac contraction from an accumulation of acetylcholine on the cardiovascular system. Hypoxia may develop due to increased capillary permeability.

Headache, dizziness, blurred vision, tremor, paresis, mental depression, coma, delayed neuropathies, various dystonias, weakness, muscle twitching, and convulsions have all been reported with carbamate poisoning. In an outbreak of gastroenteritis reported in patrons of a Thai restaurant, it was discovered that the food had been seasoned with methomyl-contaminated salt. Patients reported dizziness (72%), headache (52%), and chills (48%). Dizziness, lightheadedness, or a feeling of disequilibrium were reported as the initial symptom in 51 cases (48%). Children may be more likely to develop CNS depression, convulsions, and hypotonia than the typical cholinergic syndrome. The absence of classic muscarinic effects has been reported in several children intoxicated with carbamate insecticides. The presence of either a cardiac arrhythmia or respiratory failure is associated with a higher incidence of fatal poisoning.

Delayed neuropathies are not usually associated with carbamate insecticides. One reason for this difference is presumed to be that "aging" of the NTE pesticide complex is a requirement for neuronal degeneration. Paradoxically, studies suggest that subgroups of carbamates may actually bind NTE and exert a protective effect against more toxic OP compounds. However, cases of possible delayed neuropathy associated with carbamates have been reported. These cases involve ingestion of carbaryl, m-tolyl methyl carbamate, and carbofuran; include both sensory and motor tracts; and tend to resolve over 3–9 months. EMG findings in these subjects are variable. The symptoms are similar to those seen with organophosphates. Behavioral toxicity following carbamate exposure is extremely rare.

Acute pancreatitis has been reported with propoxur.

Combined toxicity of organophosphate and carbamate compounds can cause multiple complications, e.g., Parkinsonism, thrombocytopenia, intermediate syndrome, and neuropsychiatric manifestations (COPIND) during acute phase, and treatment can be complicated.

Diagnosis

Carbamates inhibit neuronal and RBC AChE, and plasma cholinesterase. However, the relative rapidity with which spontaneous decarbamylation of cholinesterase takes place may result in the measurement of relatively normal RBC cholinesterase activity despite severe cholinergic symptoms if the assay is not performed within several hours of sampling. In vitro decarbamylation has been found to be promoted by dilution of the sample. The carbamylated sample should be stored undiluted and refrigerated or frozen. As in the case with OP pesticide poisoning, the wide "normal" range of cholinesterase values may make interpretation of cholinesterase activity difficult at times when the patient's baseline values are unknown. Unlike OP pesticides, carbamates generally do not cause persistent depressed RBC and plasma cholinesterase activities.

Rotenberg et al. proposed an assay technique to distinguish between carbamate and organophosphate poisoning. Carbamylated cholinesterase activity follows a nonlinear kinetic pattern over time, whereas phosphorylated enzyme activity is linear. At an inhibition of greater than 40%, the nonlinear pattern characteristic of carbamates is easily mapped.

The atropine challenge test, as described for diagnosis of OP pesticide poisoning (in the previous section), can be done in carbamate poisoning also.

One technique for assessing absorption of the principal N-methyl carbamate compounds is measurement of specific phenolic metabolites in urine, e.g., carbaryl (alpha-naphthol), carbofuran (carbofuran phenol) propoxur (isopropoxyphenol).

Chest X-ray should be obtained in all symptomatic patients. The major cause of morbidity and mortality in carbamate insecticide poisonings is respiratory failure and associated pulmonary edema.

Treatment

An important differentiating point from organophosphates is that oximes are generally not recommended, while atropine can be given.

Especially in carbaryl poisoning, oxime therapy can lead to the production of a carbamylated oxime which may be a more potent AChE inhibitor than carbaryl itself. With other carbamate insecticides (particularly aldicarb), oximes may be a useful adjunct to atropine therapy. The current consensus is that pralidoxime can be used in conjunction with atropine for specific indications as follows:

- Life-threatening symptoms such as severe muscle weakness, fasciculations, paralysis, or decreased respiratory effort
- Continued excessive requirements of atropine
- Concomitant organophosphate and carbamate exposure

Fortunately, because of the rapid hydrolysis of the carbamate-AChE complex, symptoms, including weakness and paralysis, usually resolve within 24–48 hours without pralidoxime therapy. However, administering pralidoxime to a poisoned patient in a cholinergic crisis is appropriate when it is not known whether the patient is suffering from OP or carbamate pesticide poisoning. If the poisoning is from a carbamate pesticide, pralidoxime therapy may not be

necessary, but if used, should not prove detrimental. Second, significant inhibition of RBC cholinesterase and plasma cholinesterase by carbamates generally does not last for >1–2 days, assuming absorption is complete. Patients exposed to carbamates usually have normal values by the time of discharge. There are no reported cases of recurrent or delayed poisonings following carbamate insecticide poisoning. Therefore, repeating cholinesterase tests after patients are asymptomatic is usually unnecessary.

In all cases, administer atropine in repeated doses intravenously until atropinization is achieved (indicated by drying of pulmonary secretions). *Adult dose:* 2–4 mg IV every 10–15 minutes. *Pediatric dose:* 0.05 mg/kg IV every 10–15 minutes. Convulsions can be controlled with a benzodiazepine (diazepam or lorazepam). If they persist or recur, administer phenobarbitone.

ALUMINUM PHOSPHIDE POISONING

Aluminum phosphide—solid fumigant, $AlPO_4$ tablets most commonly used as insecticides and rodenticides—is also referred to as "rice tablets," "wheat pill," celphos, and alphos as shown in **Figure 5**. Peculiar features of aluminum phosphide (**Table 5**) poisoning are as follows:

- It is kept as tablets which are used in grain storage after harvesting.
- It is found to be the most common cause of acute poisoning in India. It was also found to be the most common cause of suicidal death in North India.
- It shows a distinct male preponderance in the lower socioeconomic strata and in rural areas, probably due to the heavy social stress burden in this group.
- A positive history of ingestion is the basis of diagnosis in most cases.
- The presence of typical clinical features, garlicky odor from the mouth, and highly variable arrhythmias in a young patient with shock and no previous history of cardiac disease points toward $AlPO_4$.
- Unfortunately, its widespread use has been associated with a galloping rise in the incidence of $AlPO_4$ poisoning. Recent studies have indicated that the number of deaths so far has exceeded the number of fatalities in the Bhopal gas tragedy. The mechanism of aluminum phosphide toxicity, shown in **Flowchart 2**, consists of the release of phosphene gas, inhibition of cytochrome failure of cellular respiration, formation of highly reactive radicles, and cellular injury due to lipid peroxidation.

Clinical Features

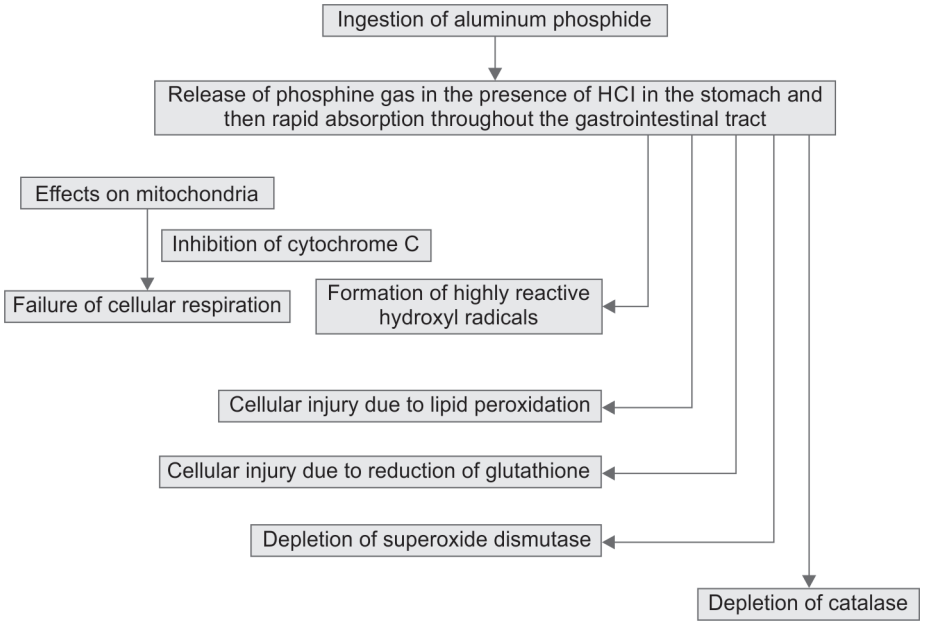
- The presenting symptoms depend on the route of administration.

FIG. 5: Tablet form of aluminum phosphide.

TABLE 5: Comparison of aluminum phosphide and organophosphorus compound.

	Aluminum phosphide	***Organophosphorus compound***
Compound	Metallic salt of phosphorus	Organic compound of phosphorus
Available	Tablets/Powder	Liquid form dissolved in kerosine
Pesticides	Fumigant in closed grain storage	Spray on open crops
Fatal	Cardiotoxic and cellulotoxic	Neurotoxic and respiratory failure
Life-saving treatment	IABP and supportive	Intubation and mechanical ventilation
Antidote	NIL	Atropine and pralidoxime
Fatal period	Within hours	Within hours
Fatal dose	1 tablet (3 g)	10–15 mL
Smell	Mousy odor	Kerosine like noxious smell

(IABP: intra-aortic balloon pump)



Ingestion of aluminum phosphide
Release of phosphine gas in the presence of HCl in the stomach and then rapid absorption throughout the gastrointestinal tract
Effects on mitochondria
Inhibition of cytochrome C
Failure of cellular respiration
Formation of highly reactive hydroxyl radicals
Cellular injury due to lipid peroxidation
Cellular injury due to reduction of glutathione
Depletion of superoxide dismutase
Depletion of catalase

FLOWCHART 2: Mechanism of aluminum phosphide toxicity.

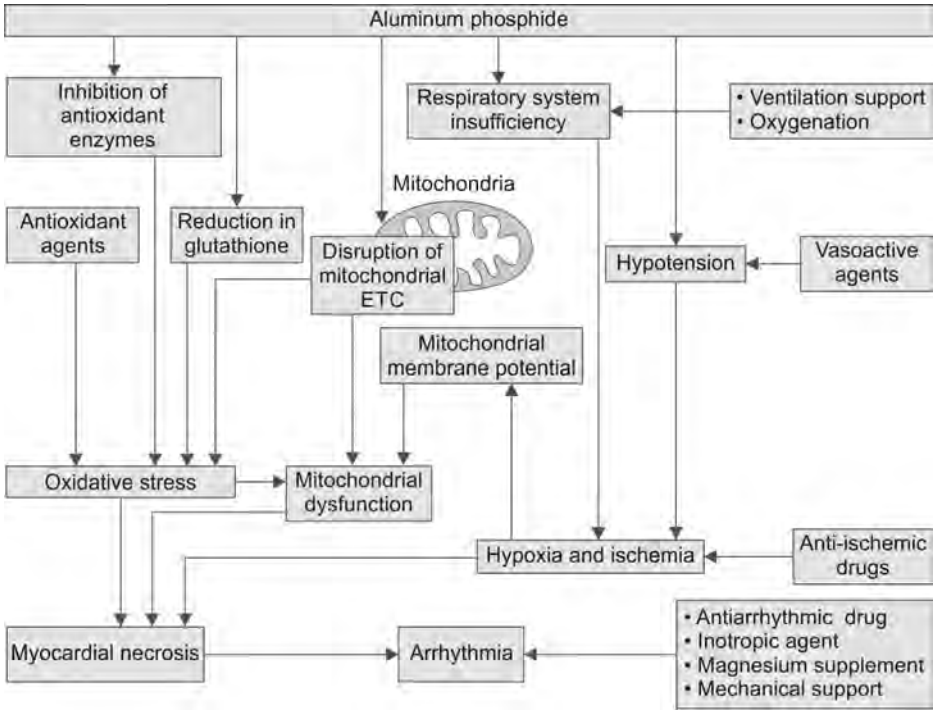
- Poisoning by inhalation produces irritation of mucous membrane, dizziness, easy fatigability, nausea, vomiting, headache, and diarrhea in mild exposure.
- Ataxia, numbness, paresthesia, muscle weakness, paralysis, diplopia, and jaundice result from a moderate degree of exposure.
- In severe cases of inhalational poisoning, the patient presents with ARDS, congestive cardiac failure, convulsion, and coma.
- Nausea, vomiting, and abdominal pain are the earliest symptoms that appear after ingestion.
- GI symptoms present in moderate-to-severe poisoning are excessive thirst, abdominal pain, and epigastric tenderness while cardiovascular abnormalities seen are profound hypotension, dry pericarditis, myocarditis, acute congestive heart failure, and arrhythmias.
- Involvement of the respiratory system may lead to dyspnea, which may progress to type I or II respiratory failure.
- Nervous system manifestations include headache, dizziness, altered mental status, convulsion, acute hypoxic encephalopathy, and coma.
- Cardiac arrhythmias, respiratory failure, metabolic acidosis. *ECG abnormalities*: Most probably due to hypomagnesemia caused by cardiotoxic effect of phosphine (**Flowchart 3**).

Diagnosis

- A positive history of ingestion is the basis of diagnosis in most cases. The presence of typical clinical features, garlicky odor from the mouth, and highly variable arrhythmias in a young patient with shock and no previous history of cardiac disease points toward $AlPO_4$ poisoning.
- Confirmation can be done by the silver nitrate test. In this test, 5 mL of gastric aspirate and 15 mL of water are put in a flask and the mouth of the flask is covered by filter paper impregnated with 0.1 N silver nitrate. The flask is heated at 50°C for 15–20 minutes. If phosphine is present, the filter paper turns black. For performing the test on exhaled air, the silver nitrate impregnated filter paper is placed on the mouth of the patient and the patient is asked to breathe through it for 15–20 minutes. Blackening of the paper indicates the presence of phosphine in breath. The sensitivity of the test is 100% and 50% vis-à-vis gastric fluid and exhaled air, respectively.
- However, the most specific and sensitive method for detecting the presence of pH in blood or air is gas chromatography.
- For spot sampling of phosphine in air, detector tubes and bulbs are available commercially.
- Laboratory evaluation is mainly done to assess the prognosis.
- Leukopenia indicates severe toxicity.
- Increased SGOT (serum glutamic oxaloacetic transaminase) or SGPT (serum glutamic-pyruvic transaminase) and metabolic acidosis indicate moderate-to-severe ingestional poisoning.
- Electrolyte analysis shows decreased magnesium while potassium may be increased or decreased.
- Measurement of plasma renin is significant as its level in blood carries a direct relationship with mortality and is raised in direct proportion to the dose of pesticide.
- The serum level of cortisol is usually found to be decreased in severe poisoning.

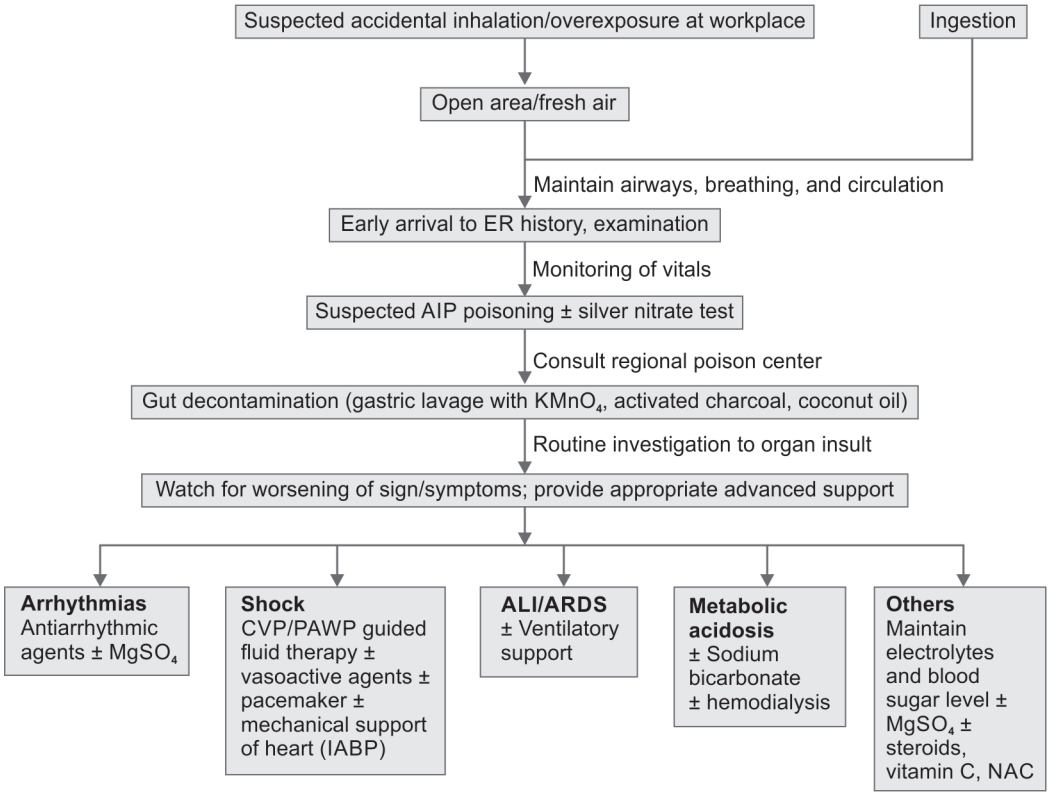
Emergency Department Management of Aluminium Phosphide Poisoning

- Take personal protection measures, including a full-face mask and rubber gloves during decontamination. Secure airway; if required patient should be intubated and mechanically ventilated, there is no role of noninvasive ventilation in $AlPO_4$ poisoning, central venous line should be preferred as IV access (**Flowchart 4**).
- IV access should be established and 2–3 L of normal saline is administered within the first 8–12 hours.
- Vasopressor is started to keep systolic blood pressure >90 mm Hg.
- Gut decontamination with $KMnO_4$, vegetable or coconut oil (within 6 h)



(ETC: electron transport chain)

FLOWCHART 3: Effect of aluminum phosphide on the cardiovascular system causing hypotension and arrhythmias.



Suspected accidental inhalation/overexposure at workplace
Ingestion
Open area/fresh air
Maintain airways, breathing, and circulation
Early arrival to ER history, examination
Monitoring of vitals
Suspected AIP poisoning ± silver nitrate test
Consult regional poison center
Gut decontamination (gastric lavage with $KMnO_4$, activated charcoal, coconut oil)
Routine investigation to organ insult
Watch for worsening of sign/symptoms; provide appropriate advanced support
Arrhythmias
Antiarrhythmic agents ± $MgSO_4$
Shock
CVP/PAWP guided fluid therapy ± vasoactive agents ± pacemaker ± mechanical support of heart (IABP)
ALI/ARDS
± Ventilatory support
Metabolic acidosis
± Sodium bicarbonate
± hemodialysis
Others
Maintain electrolytes and blood sugar level ± $MgSO_4$ ± steroids, vitamin C, NAC

(ALI: acute lung injury; $AlPO_4$: aluminum phosphide; ARDS: acute respiratory distress syndrome; CVP: central venous pressure; PAWP: pulmonary capillary wedge pressure; NAC: n-acetyl cysteine)

FLOWCHART 4: Emergency management of aluminum phosphide poisoning.

- Two important steps, resuscitation of shock and supportive measures, should be taken as soon as possible. In management, the main objective is to provide oxygenation, ventilation, and circulation till phosphine is excreted. Specific management toward $AlPO_4$ toxicity includes reducing absorption of phosphine, reducing cellular toxicity, and increasing excretion through kidney and lungs.
- Various point-of-care devices are useful while managing the $AlPO_4$ poisoning are electrocardiogram, arterial blood gas analysis, ultrasound chest, echocardiography, cardiac enzymes, portable chest X-ray.
- After ingestion, effectiveness of gut decontamination primarily depends on the duration of exposure of poison and should be done as early as possible.
- To reduce the absorption of phosphine, gastric lavage is done with coconut oil.
- Gastric lavage with normal saline or distilled water is contraindicated as phosphine gas is liberated from $AlPO_4$ on coming in contact with water.
- Potassium permanganate (1:10,000) can be used for gastric lavage as it oxidizes phosphine to nontoxic phosphate. There is no well-proven basis to conclude that $KMnO_4$ is efficient against $AlPO_4$ poisoning.
- Slurry of activated charcoal also helps to adsorb phosphine from the GI tract in most of the literature. Activated charcoal has a wide internal surface area consisting of pores (10–20 Å). It efficiently adsorbs toxins of moderate molecular weight (100–800 Da). The molecular weight of $AlPO_4$ is about 58 Da; therefore, the role of activated charcoal in $AlPO_4$ poisoning is again doubtful as liberated phosphine cannot be detoxified.
- Magnesium sulfate helps in scavenging free radicals through glutathione (GSH) recovery; hence, it is effective as a parenteral antioxidant in this poisoning as well as has been tried for its general membrane-stabilizing effect in cardiac cells. It is observed that dose-related mortality rates in patients treated with and without $MgSO_4$ are not significantly different. Magnesium is a weak antiarrhythmic agent and may be useful in controlling few supraventricular arrhythmias and a more potent antiarrhythmic agent can be used.
- Antacids and proton-pump blockers are added for symptomatic relief.

Intensive Care Management of Aluminium Phosphide Poisoning

- *Shock*: Fluid therapy with 2–3 L normal saline in the first 8 hours to maintain CVP of 12–14 cm saline. Adequate hydration and renal perfusion with IV fluid enhance the excretion of poison through urine.
- *If no response*: Inotropes can be added to keep systolic blood pressure >90 mm Hg.
- *Refractory hypotension*: Consider intra-aortic balloon pump (IABP). The role of advanced measures such as the use of IABP to mechanically support the heart has been practiced in tertiary care hospitals. The role of advanced measures such as the use of IABP to mechanically support the heart has been demonstrated in toxic myocarditis with refractory shock due to aluminum phosphide poisoning. IABP can mechanically support the heart, decrease the afterload, and improve perfusion to the vital organs and coronary arteries.
- The possibility of the beneficial effect of extracorporeal life support (ECLS) as a supportive measure for intractable circulatory collapse. Extracorporeal membrane oxygenation (ECMO) is a novel technique for supplying oxygen and it may have a beneficial role in the management of $AlPO_4$ poisoning.

Aluminum phosphide poisoning has a high mortality rate due to the nonavailability of a specific antidote. Only possible measures to save the life in poisoning with unexposed forms of aluminum phosphide are supportive.

SUMMARY

Poisoning is a major global problem and specially in India due to pesticides, its incidence is increasing due to fast industrialization and urbanization. The toxins involved in acute poisoning cases vary from place to place but in India, insecticides and pesticides are the most commonly consumed agents, e.g., organophosphorus carbamate and aluminium phosphide. Number of cases are increasing day-by-day so knowledge of commonly consumed poisons in India particularly important for emergency physicians as it may help in early diagnosis and institution of life-saving treatment.

201 CHAPTER

Anticholinergics

Shikha Tandon

INTRODUCTION

Anticholinergics are substances that block the neurotransmitter acetylcholine in the central and peripheral nervous systems and are administered to reduce the effects mediated by acetylcholine on acetylcholine receptors in neurons through competitive inhibition. There are many medications and plants in which anticholinergic properties are present. Anticholinergic activities can be seen either as therapeutic effects or due to adverse events. Antihistamine or accidental ingestions of hyoscyamine-containing drug by a child to treat colic pain can present as toxicity.

Various plants and their components also have anticholinergic properties and produce a psychoactive hallucinogenic effect if ingested accidentally or taken as abuse. Alkaloids containing plant belladonna have high anticholinergic properties. Ingestions of seeds and berries can also produce anticholinergic toxicity. Atropine is the antidote for organophosphorus insecticides which produces cholinergic syndrome. Anticholinergic toxicity can also be observed on a high dose of atropine given to a person without cholinesterase poisoning.

HISTORY

Historically, anticholinergic agents were known more for their toxicity than for their therapeutic effects. Anticholinergics originate from botanical preparations of the deadly nightshade family (Solanaceae) used for centuries in many cultures. *Datura* is a genus of the Solanaceae family and it grows worldwide. The burning roots, stems, and seeds of these plants release an aerosol of potent alkaloids, one of which is the antimuscarinic compound, atropine. It was the inhalation of this medicinal smoke that was a treatment for obstructive airways disease for many centuries. In addition to atropine, other alkaloids, including scopolamine and hyoscyamine, are released with additional effects including intoxication, hallucinations, and poisoning.

PHARMACOLOGY

The absorption of anticholinergics drugs is through ingestion, smoking, and ocular route. Anticholinergics act as reversible competitive antagonists to the neurotransmitter acetylcholine, thus blocking it to bind at cholinergic receptors present in the endings of the parasympathetic nervous system. There are 2 types of cholinergic receptors described in **Table 1**. Anticholinergics can be broken down into three subgroups based on their respective specificity to various types of cholinergic receptors.

The first group of "classic" anticholinergic agents is the antimuscarinic compounds (atropine, propantheline), which block acetylcholine action, or the cholinomimetic drugs, which bind to muscarinic M-receptive areas of the central nervous system (CNS) and glandular system, myocardium, and smooth muscle.

The second group is represented by ganglioblockers (mecamylamine, trimethaphan), which inhibit cholinergic

TABLE 1: Types of cholinergic (muscarinic and nicotinic) receptors.

Receptors	*Location*	*Stimulates/Action*
Muscarinic	M_1 brain salivary gland	Increases salivary and gastric secretion
	M_2 heart	Decreases in sinus and atrioventricular node rate
	M_3 smooth muscle cells endocrine and iris	Bronchospasm, increase saliva and gastric acid, constriction of the pupil
	M_4 central nervous system	Multiple actions
	M_5 not well understood	Mechanism of action—activation of phospholipase C—increase calcium and decrease in cyclic adenosine monophosphate
Nicotinic	• Central nervous system • Neuromuscular junction • Autonomic ganglion • Adrenal medulla	Mechanism of action—opening of Na and K channels—depolarization

transmission in the autonomic parasympathetic and sympathetic ganglia by blocking (nicotinic) N-receptors.

The third group is represented by neuromuscular junction blockers (tubocurarine, pancuronium), which block nicotinic N-receptors of skeletal muscle.

ETIOLOGY OF ANTICHOLINERGIC TOXICITY

Anticholinergic toxicity is common in the emergency department (ED) but rarely fatal. Overdoses of compounds with anticholinergic activity can be accidental or intentional. This is an important issue as anticholinergics are readily accessible, and many medications/over-the-counter (OTC) drugs have anticholinergic side effects, such as those used in the treatment of motion sickness, nausea, insomnia, parkinsonism, etc.

The majority of anticholinergic agents are orally ingested. The naturally occurring compounds atropine, hyoscyamine, and scopolamine are the prototypical anticholinergics from which others are synthesized. The prototypical agent atropine is used as an antidote for cholinergic toxicity from organophosphates and nerve agents which is a common scenario in developing nations. Atropine is also used as an acute treatment for symptomatic bradyarrhythmia as per the advanced cardiac life support (ACLS) algorithms.

Other therapeutic uses of anticholinergics include antihistamines, antiparkinson drugs, sleep aids, antiemetics, drugs for overactive bladder, tricyclic antidepressants (TCAs), muscle relaxants, and antipsychotics. The effects of multiple anticholinergic medications are synergistic. This is especially important for elderly patients on multiple medications. The most common source of an anticholinergic drug overdose is antihistamines.

Plants are also a common source of accidental and intentional anticholinergic ingestion. Plants that contain belladonna alkaloids are often abused due to their hallucinogenic properties.

HISTORY AND EVALUATION

A thorough history and physical examination are critical to the identification of patients with anticholinergic poisoning. Patients may present with a history of intentional ingestion of common anticholinergic agents such as antihistamines or jimson weed. There are various groups of prescription drugs in which anticholinergic activities are present and overdose can produce toxicity listed in **Table 2**.

Often, the history is less straightforward. Patients may present after a suicide attempt and be unwilling or unable to disclose what they ingested. Young children may be brought in by a caretaker/parent with somnolence/decreased mentation or other anticholinergic symptoms, although the ingestion may have been unwitnessed by the caretaker. Any history of potential co-ingestion should be obtained [commonly antidepressants, benzodiazepines (BDZs), alcohol, other sedatives, etc.].

Due to potential difficulty in obtaining a reliable history, it is critical that the clinician be familiar with the anticholinergic toxidrome. The memory aid "*red as a beet, dry as a bone, blind as a bat, mad as a hatter, hot as a hare, full as a flask*" is helpful to remember the classic signs and symptoms of anticholinergic poisoning.

TABLE 2: Commonly prescribed drugs with anticholinergic properties.

Class	*Drugs*
Antihistamine	Chlorpheniramine, loratadine, cetirizine, meclizine, prochlorperazine, promethazine
Antispasmodic	Dicyclomine, methantheline bromide
Antipsychotics	Chlorpromazine, thioridazine, clozapine, olanzapine quetiapine
Antidepressant	Amitriptyline, imipramine, doxepin
Anti-Parkinson drugs	Benztropine, trihexyphenidyl
Skeletal muscle relaxant	Cyclobenzaprine, orphenadrine
Mydriatic	Cyclopentolate, tropicamide
Belladonna alkaloids	Atropine, homatropine, scopolamine, glycopyrrolate
Plants	• *Datura* species—*Datura stramonium* • Mandragora/Mandrake • *Brugmansia* species

CLINICAL FEATURES

The signs and symptoms of anticholinergic toxicity are due to the blockage of central and peripheral cholinergic receptors. Central anticholinergic syndrome presents as fever agitation, delirium, and coma while peripheral anticholinergic syndrome presents as tachycardia, dry and flushed skin, dry mouth, and urinary retention.

Clinical findings associated with toxicity of cyclic antidepressant are more of wide complex tachydysrhythmia along with anticholinergic effect. An injectable antihistamine may present with euphoria in the patient.

A delirium patient with central anticholinergic syndrome presents with restlessness, irritability, disorientation, confusion, agitation, auditory, and visual hallucination. Repetitive picking of bed cloth or imaginary objective is common. Staccato speech pattern, dysarthria, unable to comprehend, high-pitched cries, jerking movement of extremities, and seizure can be seen.

Hyperthermia can also be seen which is usually agitation induced, associated with other symptoms such as decreased sweating and movement. Hyperthermia leads to rhabdomyolysis, coagulopathy, and multiorgan dysfunction. Mortality is due to status epilepticus, hyperthermia, wide complex tachydysrhythmia, and cardiovascular collapse.

DIFFERENTIAL DIAGNOSIS

Many conditions can cause agitated delirium, especially in the elderly. The side effects of other medications and polypharmacy should be considered. Pure anticholinergic toxicity versus mixed toxicity, as seen with TCAs and phenothiazines, should be considered. Common distractors in making a diagnosis of anticholinergic toxicity are neuroleptic malignant syndrome (antipsychotics such as haloperidol, phenothiazines such as promethazine, chlorpromazine), malignant hyperthermia (depolarizing muscle relaxants, anesthetics such as halothane/isoflurane/desflurane), serotonin syndrome (antidepressants, opioids, CNS stimulants), etc. Overlapping features make it

TABLE 3: Differentiating features of anticholinergic toxicity from other conditions.

Conditions	*Exposure to medications*	*Common features*	*Differentiating features*
Serotonin syndrome	Serotonergic medications	Hypertension	Presence of clonus hyperreflexia, hyperactive bowel sound
Neuroleptic malignant syndrome	Dopamine agonist	Tachycardia	Bradykinesia, no clonus or hyperreflexia
Anticholinergic toxicity	Acetylcholine antagonist	Hyperthermia	Dry skin, absent bowel sound, no clonus, or hyperreflexia
Malignant hyperthermia	Muscle relaxant anesthetic agents	Altered mental status	Extreme muscle rigidity, no clonus or hyperreflexia

confusing unless a thorough clinical history and distinguishing features of each of the poisonings have been kept in mind and catered to while examining the patient. The same has been enumerated in **Table 3**.

MANAGEMENT

Good supportive care is usually all that is required for the treatment of anticholinergic toxicity. Pharmacological sedation with BDZs (lorazepam and diazepam) is strongly recommended and used to counteract agitation of the patient and seizure activity. Intravenous fluid is to be started in case of hypotension and if there is any rhabdomyolysis. Adequate cooling techniques are to be used in case of hyperthermia, and activated charcoal can be administered if the ingestion has been within an hour of presentation to the ED. Soda bicarbonate can be given in case of wide complex tachyarrhythmias.

However, physostigmine may be indicated in severe cases as a specific antidote. Physostigmine is not generally considered a first-line agent and should probably be reserved for cases with potentially life-threatening complications of anticholinergic toxicity that are unresponsive to standard treatment regimens such as severe agitation, seizures, persistent hypertension, and hemodynamic compromise secondary to tachycardia (i.e., unstable narrow complex dysrhythmias). The recommended dose is 0.5–2 mg IV for adults and 0.02 mg/kg IV for pediatric patients with a maximum pediatric dose of 0.5 mg. Because of its short half-life and rapid elimination, repeat dosing may be required after approximately 30 minutes if symptoms recur.

This is hence used as a specific antidote keeping the following important considerations:

- Severe agitation or psychosis unresponsive to other therapies.
- Severe peripheral and central anticholinergic features.
- No history of seizures (rapid infusion in ED can precipitate/induce seizures).
- Normal electrocardiogram (EKG), especially QRS duration (conditions with QRS >0.10 s are associated with brady arrhythmias and asystole).
- No co-ingestion of drugs altering intraventricular conduction, e.g., TCAs, the toxicity of which is associated with QRS prolongation primarily.

Prior to administering physostigmine in the ED, potential complications in the form of increased cholinergic tone should be anticipated. Urinary outlet obstruction can be prevented by the placement of a Foley catheter beforehand and bedside suction should be immediately available to clear excessive salivation, bronchial secretions, or emesis. The patient should be placed on continuous EKG and pulse oximetry monitoring. Close supervision during and immediately following administration is desirable. Resuscitation equipment including atropine should also be readily available to counteract the cardiac side effects of excessive cholinergic tone.

The final disposition of poisoning cases should be an admission in the intensive care unit. Besides the therapeutic measures, other aspects also need to be addressed. A poison control center must be informed and a psychiatry consultation to be sought in cases of intentional self-harm. Elderly population must be educated about the fact that taking multiple medications carries a risk of anticholinergic side effects. Parents must be educated to keep common OTC drugs out of reach of children. People should also be made aware that commonly prescribed drugs, such as cold medications and sedatives, should not be consumed at doses more than prescribed. The key points of treatment are given in **Table 4**.

DISPOSITION

Patients with anticholinergic toxicity with mild symptoms can be discharged to home after a 6-hour observation in the ED. The rest of the patients with anticholinergic toxicity should be hospitalized till the resolution of symptoms or 12 hours after receiving the physostigmine.

SUMMARY

Always consider anticholinergic toxicity in patients taking multiple medications, especially the elderly; hence, polypharmacy should be ruled out. Always consider anticholinergic toxicity in young children who present somnolent or lethargic. Remember the mnemonic "*red as a beet, dry as a bone, blind as a bat, mad as a hatter, hot as a hare, stuffed as a pipe*." There is as such no confirmatory testing readily available in the emergency setting. Anticholinergic toxicity is a clinical diagnosis.

TABLE 4: Key points for anticholinergic toxicity treatment.

Intervention/Drug	*Action*	*Rationale*
Activated charcoal	For gastrointestinal decontamination	Decreased intestinal motility may enhance its effect
Sedation	Benzodiazepines	Strongly recommended to avoid injury in an agitated patient, risk of hyperthermia and rhabdomyolysis can be avoided
Sodium bicarbonate	Wide complex tachyarrhythmias	Severe cases of anticholinergic toxicity present with wide complex arrhythmias due to sodium channel blockade
Cholinesterase inhibition	Physostigmine	Used in severe anticholinergic toxicity with severe agitation and unresponsive to other therapies

202
CHAPTER

Antidepressant Antipsychotic

Devendra Richhariya

INTRODUCTION

Antidepressants and antipsychotics are the two most commonly prescribed drugs so emergency physicians should be aware of their potential side effects, multidrug exposure, overdose effects, and toxicity by both therapeutic doses and intentional ingestions.

ANTIDEPRESSANT

Depression is probably one of the oldest diseases of mankind and *Papaver somniferum* is the oldest antidepressant. It was postulated that cerebral monoamine neurotransmitter deficiency is the cause of depression. But now depression is observed as a complicated picture of receptor-neurotransmitters biochemistry and gene expression. Over the years, many pharmacological agents have also evolved to treat the many symptoms of depression.

Antidepressants are drugs that are used in depressive illness for the elevation of the mood. Generally, all antidepressants act directly or indirectly by affecting the monoaminergic transmission in the brain. Over the last two decades, various antidepressants are available and classified (**Table 1**) on the basis of reuptake/metabolism of biogenic amines or pre/post aminergic/cholinergic receptors.

Monoamine oxidase inhibitors (MAO-I) and tricyclic antidepressants (TCA) are considered first-generation antidepressants and their use has declined over the years and have been largely replaced by the newer, second-generation, atypical, serotonergic antidepressant which has a unique pharmacological effect on serotonin–norepinephrine dopamine modulation in the brain.

OVERDOSE AND TOXICITY

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors are the first-generation antidepressant and are currently used to treat only atypical and refractory cases of depression as newer antidepressants have better and favorable side-effect profile, less toxicity on overdose, and no dietary restrictions. Isocarboxazid, selegiline, rasagiline, moclobemide, and phenelzine are a few examples of the MAO-I. Tyramine reaction, serotonin syndrome, and medication incompatibilities are associated with MAO-I, and "even one pill can kill" the pediatric age group population.

There is no typical presentation of symptoms of MAO-I overdose and toxicity, and symptoms' presentation is also delayed 6–12 hours (even 24 hours) after ingestions. Headache, agitation irritability, nausea, palpitation, and tremor are the initial presentations. Tachycardia, hyperreflexia, hyperactivity, fasciculation, dilated pupil, nystagmus, and flushing are the *early signs of toxicity*. Muscle rigidity, chest pain, hypertension, diarrhea, hallucination, confusion, and agitation are the features of *moderate toxicity*. Coma, seizures, hypotension, hypoxia, bradycardia, and hyperthermia are the features of

TABLE 1: Practical classification of antidepressants.

Tricyclic antidepressant (TCA)	*Atypical antidepressant*	*Selective serotonin reuptake inhibitors (SSRIs)*	*Serotonin/norepinephrine reuptake inhibitors (SNRIs)*
• Monoaminoxidase inhibitors (MAO-I) and TCA are considered first-generation antidepressants • Amitriptyline, imipramine, clomipramine, trimipramine, doxepin, dothiepin • Nortriptyline, desipramine, amoxapine, reboxetine	• Also known as newer/second-generation/serotonergic antidepressants • Bupropion, mirtazapine, nefazodone • Trazodone, vilazodone, vortioxetine	• Citalopram, escitalopram, fluvoxamine, fluoxetine • Sertraline, paroxetine	• These are also called nonselective inhibitors of serotonin and norepinephrine • Desvenlafaxine, duloxetine, levomilnacipran, venlafaxine

severe toxicity. QT prolongation is specific to moclobemide overdose and toxicity.

Tyramine Reaction

Tyramine is an exogenous dietary amine present in a small amount in many foods but in a high amount in pickled and fermented dietary products. It is normally metabolized by the intestine and hepatic monoamine oxidase, and this process prevents tyramine from entering into the blood. But this process is lost by nonselective MAO-I and gives rise to tyramine reaction. Tyramine reaction is rapid onset within 15–60 minutes of ingestion of amine-containing food. The severity of the reaction depends on the amount of tyramine-containing food ingested. Severe occipital or temporal headache is a typical symptom of tyramine reaction. Other features are hypertension, palpitation chest pain, pallor, neck stiffness, diaphoresis, and mydriasis. Within 6 hours, most symptoms resolve without any treatment but in rare cases, some fatality is reported due to myocardial infarction and intracranial hemorrhage. Electrocardiogram (ECG) should be performed in cases of chest pain and computed tomography (CT) of the head should be performed if a severe headache is reported. Severe hypertension is treated with phentolamine 2.5–5 mg IV every 5–15 minutes until blood pressure is controlled. A rapid-acting direct vasodilator, nitroprusside, can be used 1–4 μg/kg/min IV infusion.

Tricyclic Antidepressant

Although the popularity of TCAs has decreased in recent years, they remain a frequent cause of drug exposure and overdose, in most cases requiring emergent medical care. TCAs are associated with more drug-related deaths than any other class of prescription medication. The relatively low exposure-to-death ratio of TCAs underscores their low therapeutic index and potential for severe toxicity resulting in death. In addition, they are prescribed frequently for other psychiatric and medical conditions such as obsessive-compulsive disorder, attention-deficit disorder, panic and phobia disorders, anxiety disorders, eating disorders, chronic pain syndromes, peripheral neuropathies, nocturnal enuresis, migraine headache prophylaxis, and selected drug withdrawal therapy.

Pediatric and adolescent use has increased significantly over the past few years. The five most commonly reported TCAs involved in drug exposures include (1) amitriptyline (40%), (2) imipramine (17%), (3) doxepin (14%), (4) nortriptyline (12%), and (5) desipramine (6%).

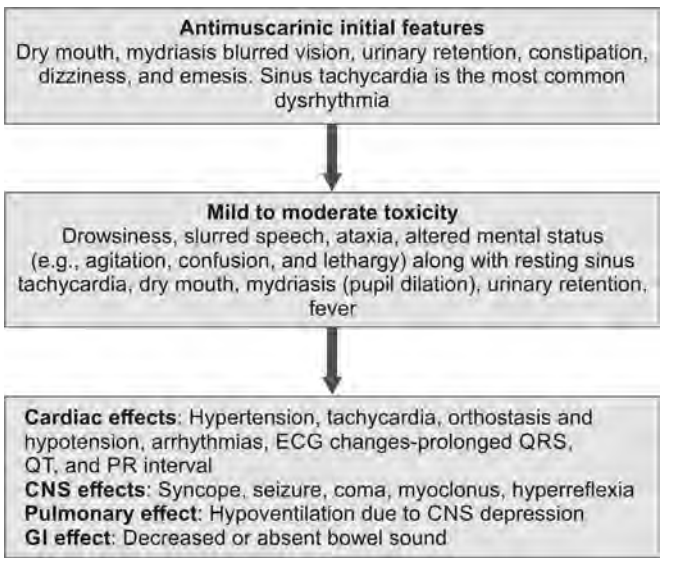
There are different possible *mechanisms for developing TCA-related drug toxicity* while taking therapeutic doses. *First*, mild-to-moderate toxicity will develop commonly if unacclimated individuals are started on higher therapeutic doses. *Second,* toxicity can result when TCAs are combined with other medications having similar pharmacologic actions (e.g., antihistamines, antipsychotics). *Third,* in the population in which TCAs metabolize slowly, higher plasma TCA levels achieved for any given dose. *Fourth,* drug combination formulations with either benzodiazepines or antipsychotic agents have the potential for additional drug toxicity. *Fifth,* patients with comorbidity conditions, such as underlying heart problems or seizure disorders, are more susceptible to TCA toxicity at therapeutic doses. *Sixth*, TCAs with other serotonergic medications produce serotonin syndrome.

Clinical Features and Diagnosis of Tricyclic Antidepressant Toxicity

Tricyclic antidepressant at a therapeutic dose of <1 mg/kg is not toxic. Ingestion of >10 mg/kg TCA is life-threatening. Geriatric and pediatric age group population; patients on cardiotoxic, sedative, and antipsychotic drugs; and patients with an underlying heart and neurologic disease are at a higher risk of developing TCA toxicity (**Flowchart 1**). A combination of the following four criteria is essential for the diagnosis of TCA toxicity: (1) history of TCA drug intake, (2) clinical features, (3) typical ECG findings, and (4) positive urine drug screen for TCA.

Atypical Antidepressant

Atypical antidepressants are also known as *second-generation or newer antidepressants,* and most of them pose serotonergic activities. They are the most popular form of psychopharmacological therapy for major depression, obsessive-compulsive disorder, panic disorder, and eating disorder. *Second-generation, newer or atypical serotonergic antidepressants* are less severe toxic in overdose and are less fatal than TCA and MAO-I. These groups have serotonergic activities and the potential to cause *serotonergic syndrome* in combination with other serotonergic agents. These classes of drugs do not produce tyramine reaction (do not inhibit monoamine oxidase) and also not much inhibition of the cardiac, sodium, calcium, or potassium ion channel. Generalized overdose and toxic symptoms are dizziness, tremor, nausea, vomiting, tachycardia, agitation, and mild hyperthermia. Seizure is more common in bupropion toxicity in comparison to another atypical antidepressants. ECG changes, hypotension, coma, and cardiac arrest are also reported in severe bupropion toxicity. Central nervous system (CNS) depression (dizziness and ataxia) is significant in trazodone atypical antidepressant. Drug-induced priapism is also noted in trazodone atypical antidepressant.



Antimuscarinic initial features
Dry mouth, mydriasis blurred vision, urinary retention, constipation, dizziness, and emesis. Sinus tachycardia is the most common dysrhythmia
Mild to moderate toxicity
Drowsiness, slurred speech, ataxia, altered mental status (e.g., agitation, confusion, and lethargy) along with resting sinus tachycardia, dry mouth, mydriasis (pupil dilation), urinary retention, fever
Cardiac effects: Hypertension, tachycardia, orthostasis and hypotension, arrhythmias, ECG changes-prolonged QRS, QT, and PR interval
CNS effects: Syncope, seizure, coma, myoclonus, hyperreflexia
Pulmonary effect: Hypoventilation due to CNS depression
GI effect: Decreased or absent bowel sound

(CNS: central nervous system; ECG: electrocardiogram; GI: gastrointestinal; TCA: tricyclic antidepressant)

FLOWCHART 1: Features of TCA toxicity.

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitor (SSRIs) are a class of drugs that are typically used as antidepressants in the treatment of major depressive disorder and anxiety disorders. SSRIs are the group of antidepressants that act by inhibiting the presynaptic serotonin reuptake without much affecting norepinephrine and dopamine reuptake. They are associated with fewer overdose toxicity and other unwanted pharmacological actions as compared to TCA. Citalopram, escitalopram, fluoxetine, and sertraline are the commonly used SSRIs for depression.

Patients on SSRI complain about various adverse effects such as nausea, vomiting, diarrhea, and constipation. Neurological symptoms such as headache, dizziness, weakness, sedation, fatigue, and tremor are also reported. Extrapyramidal symptoms such as dystonic reaction, akathisia, dyskinesia hypokinesia, and Parkinsonism are also associated with SSRI therapy. Serotonin syndrome is the most serious drug-related adverse effect of SSRI. Fluoxetine is widely used and there is more clinical experience about overdose features. Agitation, seizures, hallucination, hypertension, and hypotension are less frequently observed and all SSRIs show a high therapeutic index. QT and QRS prolongation is more frequently associated with citalopram and escitalopram ingestion.

Serotonin/Norepinephrine Reuptake Inhibitors

Serotonin/norepinephrine reuptake inhibitors (SNRIs) are nonselective inhibitors of serotonin and norepinephrine uptake and no direct effect on presynaptic or postsynaptic neurotransmitter receptors. SNRIs cause tachycardia, hypertension, diaphoresis, tremor, and mydriasis which are the initial clinical features. Altered consciousness and mild-to-moderate sedation are common and progression to coma is rare. Generalized seizure and subclinical rhabdomyolysis are observed in venlafaxine overdose. Severe left ventricular dysfunction and low ejection fraction are observed in large overdose of venlafaxine. Sinus tachycardia and prolonged QRS and QT interval are common ECG abnormalities.

TREATMENT

General Management

Evaluation of the patient should be started by history-taking and physical examination. Altered mental status, hemodynamic status, and respiratory distress should be evaluated. Establish the peripheral venous access and start the intravenous fluid. Start monitoring the cardiac rhythm and take the 12-lead ECG. Arterial blood gas analysis is recommended in a symptomatic patient. Laboratory investigations such as serum electrolyte, creatinine, and blood glucose are recommended. Bladder catheterization (in case of urinary retention as antimuscarinic effect) and nasogastric tube placement (in case of ileus) is recommended. Symptoms generally appear late in initially asymptomatic patient so the patient should be monitored.

Gastrointestinal Decontamination

If the patient is awake, then patent airway and arrival to the emergency department within 1 hour of ingestion are recommended. Activated charcoal of 1 g/kg single dose should be given orally. Activated charcoal bind with TCA and help in decreasing the absorption. An asymptomatic patient with a reliable history of antidepressant overdose can be treated only with activated charcoal. Observe him/her for toxicity.

Sodium Bicarbonate

Cardiac arrhythmias (sinus tachycardia, QT and QRS prolongation in ECG) and hypotension are common in moderate-to-severe antidepressant toxicity. Sodium bicarbonate ($NaHCO_3$) is used to treat refractory hypotension and cardiac dysrhythmias. A bolus dose of $NaHCO_3$ 1–2 mEq/kg followed by repeat dose should be given till the patient improves and blood pH is between 7.50 and 7.55. Instead of repeat boluses, $NaHCO_3$ infusion can also be started (150 mEq mixed with 1 L of 5% dextrose and infusion at the rate of 2–3 mL/kg/h). Monitor serum electrolyte during $NAHCO_3$ infusion (hypokalemia is a concern).

Altered Mental Status

A diminished level of consciousness is more frequent and rapid onset in TCA overdose. Pulmonary aspiration is common in this situation. Cardiotoxicity and seizure can be precipitated. Agitation can also be observed and can be controlled by reassurance and benzodiazepine.

Seizures

Seizures are common in the early hours of the ingestion of TCA. A detailed neurological examination should be carried out if there is repeated seizure or status. Status is particularly associated with two antidepressants, maprotiline and amoxapine. The anticonvulsant of the choice in these conditions is benzodiazepine (diazepam and lorazepam). Barbiturates are used to treat benzodiazepine-resistant seizures. Endotracheal intubation may be required in case of respiratory depression.

Hypotension

Isotonic crystalloid fluid should be started initially as bolus 10–30 mL/kg by keeping in mind pulmonary edema in impaired cardiac contractility. Intravenous $NaHCO_3$ should be considered in hypotension refractory to intravenous fluid. A vasopressor should be considered if there is hypotension refractory to both fluid and $NaHCO_3$. Other supportive therapies such as circulatory and cardiopulmonary bypass, overdrive pacing, and aortic balloon pump should be considered if hypotension refractory to all the above measures is present.

Dysrhythmias

Among all antidepressants, TCA affects heart rate conduction and contractility much more than any other group of antidepressants. Drug-induced cardiotoxicity is increased by coexisting factors such as acidosis, hypotension, respiratory depression, and seizure. First-degree atrioventricular (AV) block should be monitored closely as this may progress to complete heart block. In TCA overdose induced isolated QRS prolongation or/with minimal toxicity, the use of $NaHCO_3$ is controversial but ventricular arrhythmia is treated with $NaHCO_3$. In situations such as renal failure, pulmonary edema, and cerebral edema, where $NaHCO_3$ cannot be used, hyperventilation is an alternative therapy, though it is less effective. Hypertonic saline 3% (1–3 mL/kg over 10 min) is considered if ventricular arrhythmia refractory to $NaHCO_3$

therapy is present. Magnesium sulfate 2 g intravenous is used to treat the torsades de pointes. Overdrive pacing is considered for refractory tachyarrhythmias. All, class I and class III, antiarrhythmic β blockers and calcium channel blockers are contraindicated in TCA-induced dysrhythmias.

Lipid Emulsion

Lipid emulsion therapy is considered beneficial in antidepressant (TCA) induced toxicity because TCAs are highly lipid-soluble. At present, no convincing evidence is present for use of lipid emulsion in antidepressant (TCA) toxicity. In TCA-induced cardiotoxicity which is refractory to other measures, 20% lipid emulsion is used. A *dose* of 100 mL (1.5 mL/kg) IV bolus over 2–3 minutes is given followed by infusion 18 mL/min (total dose 10 mL/kg).

SEROTONIN SYNDROME

Serotonin is a neurotransmitter and found in the dietary intake of tryptophan and helpful in alteration of various clinical statuses such as sleep, anxiety, depression, appetite, emesis, movement disorder, and platelet function. Serotonin syndrome occurs due to the presence of excess serotonin in the blood which overstimulates the serotonin receptors in the central and peripheral nervous systems. Antidepressants (**Table 1**) are the most common drugs which are associated with serotonin syndrome. Serotonin syndrome can be life-threatening and produced by any drug or combination of serotonergic medications. Serotonergic medications other than antidepressants which have the potency to cause serotonin syndrome are *amantadine, amphetamine, bromocriptine, carbamazepine, cocaine, dextromethorphan, fentanyl, levodopa, lithium, linezolid, tryptophan, lysergic acid diethylamide, metoclopramide, pentazocine, sumatriptan, other triptans, and tramadol.*

Serotonin syndrome is a triad of altered mental status (altered cognition and behavior), abnormal neuromuscular activity, and autonomic instability. Most of the patients develop serotonin syndrome at the therapeutic doses of serotonergic drugs. Clinical features are classified into minor or major categories.

Minor clinical features are *cognitive*: insomnia, restlessness anxiety; *autonomic*: tachycardia, hypertension/hypotension, tachypnea, mydriasis; and *neuromuscular*: incoordination, akathisia. Major clinical features are *cognitive*: altered mental status, agitation; *autonomic*: hyperthermia, diaphoresis; and *neuromuscular*: muscular rigidity, hyperreflexia, myoclonus, tremor.

Serotonin syndrome develops within 2–24 hours of ingestion of serotonin medications and symptoms range from mild to severe (**Box 1**). Diagnosis of serotonin syndrome is only based on the history of ingestion of medication, clinical features, and ruling out other medical and psychiatric conditions, as no confirmatory laboratory tests for the diagnosis of serotonin syndrome are available. Differentiating features of serotonin syndrome from the neuroleptic malignant syndrome (NMS) and anticholinergic toxicity are given in **Box 2**.

BOX 1: Severity of serotonin syndrome.

***Mild*:** Mild agitation, mild fever (<40°C), tremor, myoclonus, hyperreflexia, diaphoresis, mydriasis, tachycardia, and hypertension

***Moderate*:** Marked agitation, hyperthermia (>40°C), myoclonus, hyperreflexia, ocular clonus

***Severe*:** Hyperthermia (>41°C), delirium, marked muscular rigidity, marked fluctuation in blood pressure, and heart rate

BOX 2: Differentiating features of serotonin syndrome, neuroleptic malignant syndrome, and anticholinergic toxicity.

- **Serotonin syndrome**
  - H/O serotonergic medication, onset of symptoms within 24 h
  - Myoclonus tremor and hyperreflexia
- **Neuroleptic malignant syndrome (NMS)**
  - H/O dopaminergic agonist intake or withdrawl, take days to weeks to develop symptoms
  - Bradyreflexia, bradykinesia lead pipe rigidity
- **Anticholinergic toxicity**
  - H/O anticholinergic agents, symptoms develops within 1–2 h
  - Dry skin and mucous membrane, reflexes, and muscle tone are normal

(H/O: history of)

Treatment

Discontinuation of serotonergic drugs and initiation of supportive care are the basic treatment. All patients should be hospitalized and seriously ill patients need intensive care and few patients may require endotracheal intubation and mechanical ventilation. Cardiac monitoring, peripheral venous access, and intravenous fluid should be started immediately. ECG should be obtained. External cooling measures should be applied for hyperthermia (the most common cause of death is hyperthermia). Patients with muscle rigidity, seizure, and hyperthermia should be observed for rhabdomyolysis and metabolic acidosis. *Benzodiazepine* is used to control agitation, promote muscle relaxant, and enhance patient comfort. A short-acting intravenous antihypertensive (nitroprusside and esmolol) is used for severe hypertension. A vasopressor (norepinephrine or epinephrine) is used for fluid-resistant hypotension. *Cyproheptadine* (antihistamines and serotonin antagonist) available in oral form only can be used 12 mg initially and then 2 mg every 2 hourly till improvement is seen. Supportive clinical evidence is not available for cyproheptadine use in serotonin syndrome. *Chlorpromazine* is available in a parenteral form and reported to cure serotonin syndrome but causes hypotension which is the potential disadvantage.

Usually, patients with serotonin syndrome improved within 24 hours of holding the serotonergic drugs, and future inclusion of serotonergic drugs should be avoided.

ANTIPSYCHOTICS

First-generation (typical) antipsychotics were introduced in clinical practice in 1950s for the use of positive symptoms of schizophrenia only (hallucination and delusion) and not useful for negative symptoms (apathy poverty of thought, withdrawal, poor motivation). First-generation antipsychotic has limited use and is associated with a high noncompliance rate and

treatment failure because of severe extrapyramidal side effects and tardive dyskinesia. During 1980s, second-generation or atypical antipsychotics were used. These agents have the ability to treat positive as well as negative symptoms of schizophrenia and less propensity to develop extrapyramidal symptoms and tardive dyskinesia. Traditionally, antipsychotics were termed *major tranquilizers or neuroleptics*. These drugs were used to treat other conditions as well such as nausea, vomiting, agitation, headache, suppressing the hiccups, and controlling involuntary motor disorders.

Antipsychotics effects are mediated through various receptors: Dopaminergic, α adrenergic muscarinic, histaminergic, and serotonergic. All antipsychotics bind and inhibit pre- and postsynaptic dopamine-2 (D_2) receptors.

- *First-generation (typical) antipsychotics*: Chlorpromazine, prochlorperazine, haloperidol, fluphenazine, trifluoperazine, promethazine, thioridazine
- *Second-generation (atypical) antipsychotics*: Clozapine, risperidone, olanzapine, quetiapine, ziprasidone
- *Third-generation antipsychotics*: Aripiprazole, brexpiprazole, cariprazine

The most common adverse effects due to antipsychotic overdose are CNS depression, miosis hypotension, and reflex tachycardia. Single-drug overdose is rarely fatal. CNS effects are lethargy, ataxia, dysarthria, confusion, and coma with respiratory depression. ECG changes are QT prolongation, QRS widening, and nonspecific T-wave abnormalities. Diagnosis is established by history of ingestion of antipsychotics. The following supportive laboratory tests should be performed: Blood chemistry, pregnancy test in females of childbearing age, and acetaminophen and salicylate levels if there is a history of coingestion. Perform ECG to evaluate QT interval and QRS complex.

Treatment

Treatment is generally supportive, start intravenous fluid. Cardiac monitoring, pulse oximetry, and blood glucose assessment should be considered. Consider naloxone or thiamine.

*Benzodiazepin*e, e.g., lorazepam in case of seizures, can be administered. Treat hypotension initially with the intravenous fluid and in fluid-resistant case with phenylephrine and norepinephrine.

Magnesium sulfate ($MgSO_4$) is used 2 g intravenous over 10 minutes in a patient with QT_C interval > 500 ms (is at an increased risk of developing torsades de pointes). A patient of torsades de pointes should be treated with $MgSO_4$ 2 g IV bolus followed by 2–4 mg/min. Overdrive pacing is used in refractory cases. $NaHCO_3$ is used (1–2 mEq/kg IV bolus followed by repeat boluses or continuous infusion) to treat intraventricular conduction delay (prolonged QRS) and ventricular dysrhythmias. Lidocaine can be used as an alternative for ventricular arrhythmia. Antiarrhythmic drug such as class 1A, 1C, III (amiodarone) and class IV should be avoided in antipsychotic-induced conduction abnormalities and ventricular dysrhythmias (they may potentiate cardiotoxicity).

EXTRAPYRAMIDAL SYMPTOMS

All groups of antipsychotics can produce extrapyramidal symptoms (*consist of four symptoms: (1) Acute dystonia, (2) akathisia, (3) tardive dyskinesia, and (4) drug-induced parkinsonism)*. First-generation (typical) antipsychotics are known to cause more potent extrapyramidal symptoms than second- and third-generation antipsychotics. Acute dystonia and akathisia develop early in course of therapy and are reversible while tardive dyskinesia and drug-induced parkinsonism develop after prolonged antipsychotic therapy and are unlikely to be reversible.

Acute Dystonic Reaction

There are unpleasant adverse effects of dopamine-blocking agents such as antipsychotic, antiemetics, and antidepressant drugs. These are sudden involuntary contraction of muscle or group of muscles while maintaining the normal mentation and usually occur few days to week of starting the medications. Face, tongue, neck, trunk, back, and extremity muscles are commonly affected. Treatment is by administration of drugs with central anticholinergic activities, diphenhydramine (25–50 mg IV) and benztropine (1–2 mg IV) followed by diphenhydramine 25–50 mg orally and benztropine 1–2 mg orally for 2–3 days.

DRUG-INDUCED HEAT STROKE

Heat stroke is triad of hyperpyrexia (core temperature > 41.1°C), anhidrosis, and disturbance of CNS. Temperature above 41.6–42°C causes significant systemic injury and over 49°C it almost causes immediate cell death and tissue necrosis.

Heat-related illnesses are more common in an individual with a psychiatric illness or on antipsychotic medications and in the elderly population. Anticholinergic medications also increase the risk of drug-induced heat stroke. Suppressed function of the thermoregulatory center in the anterior hypothalamus and loss of sweating ability are the main pathophysiologic mechanisms for the development of drug-induced heat stroke. Early recognition of drug-induced heat stroke is essential; it is also important to differentiate early from NMS. Early cooling is essential, otherwise there will be a high risk of progression of condition to multiorgan failure. The core temperature should be maintained between 38.5 and 39°C. Hypotension usually responds to cooling and intravenous crystalloid should be used for hypotension. Refractory hypotension is an ominous sign.

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome is a rare but fatal idiosyncratic drug reaction and is due to drug overdose. NMS usually develops soon after starting/adjusting the antipsychotic drugs, and the serum level of antipsychotic drugs remains in the therapeutic range. All typical and atypical antipsychotics can produce NMS.

Neuroleptic malignant syndrome presents with hyperthermia, muscular rigidity, autonomic dysfunction, and altered mental status. Other features are akinesia, tremor, dystonia dysphagia, dyspnea, diaphoresis, sialorrhea, incontinence, tachycardia, fluctuation of blood pressure, flushing, and pallor. Two important laboratory findings are important: (1) Leukocytosis (total leucocyte count 10,000–40,000/μg/L), and (2) Elevated serum creatine phosphokinase (CPK) level. The diagnostic criteria are summarized in **Box 3**. NMS is confused with the serotonin syndrome where the onset is rapid (2–24 hours) and associated features are

BOX 3: Diagnostic criteria for neuroleptic malignant syndrome.

***Minor features*:** Muscle cramps, tremors, tachycardia, tachypnea, hypersalivations, and increased creatine kinase (>4 times of upper limit)

***Major features*:** Hyperpyrexia >38°C (100.4°F), lead pipe muscle rigidity, psychomotor slowing altered mental status, sympathetic nervous system lability, fluctuation hypertension, urinary incontinence, recent history of dopamine agonist, withdrawal of dopamine antagonist, exposure

***Exclusion criteria*:** Rule out infectious, toxic, metabolic, or neurologic causes

nausea, vomiting, diarrhea, shivering, hyperreflexia, and less pronounced muscle rigidity and fever.

Treatment is largely supportive. Antipsychotic or any other culprit medications should be withdrawn. Any other medical conditions with similar features should be evaluated and ruled out. Sedation with benzodiazepine (lorazepam) is important to decrease the agitation and sympathetic activity. Cooling measure is applied to patient temperature in hyperpyrexia, and antipyretics are generally not beneficial. Excessive secretion, dysphagia, decreased airway reflexes, and acidosis hypoxia lead to compromise in airway and breathing, which should be anticipated and patient should be intubated and ventilated. Neuromuscular paralysis and intubation are helpful in reducing the fever and rigidity. Nondepolarizing agents (rocuronium) are preferred over depolarizing agents (succinylcholine) when a patient of NMS is intubated. Other agents used to decrease the severe muscular rigidity are *dantrolene* 1.0–2.5 mg/kg loading followed by 1 mg/kg IV every 6 hourly or *bromocriptine* 2.5 mg orally 3–4 times per day or amantadine 100 mg orally 3 times per day. Mortality in NMS is largely due to complications related to severe muscular rigidity. Muscular rigidity should be promptly reduced to avoid complications such as rhabdomyolysis, renal failure, respiratory failure, disseminated intravascular failure, and cardiovascular collapse.

SUMMARY

Antidepressants and antipsychotics are the two most commonly prescribed drug classes. Several adverse reactions are also reported due to either therapeutic doses or intentional overdoses of antidepressants or antipsychotics. Most of the time, a patient presents with no symptoms or mild symptoms which require no treatment or observation in the emergency department for few hours before discharge. Rarely a patient requires intensive care management. It is expected from an emergency physician to be aware of pharmacology, toxicity, and management of antidepressant and antipsychotic exposure.

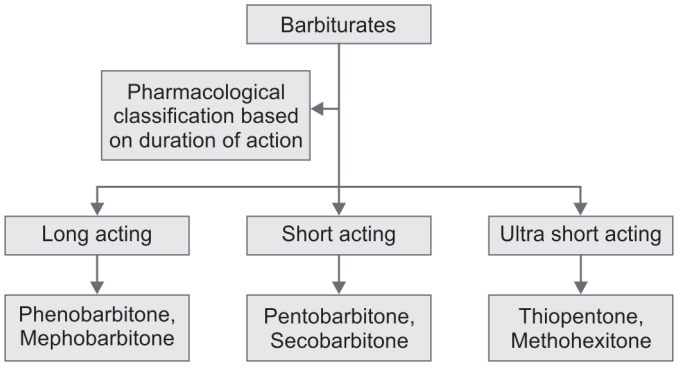
203
CHAPTER

Anticonvulsants Barbiturates and Phenytoin Toxicity

Vivekanshu Verma

BARBITURATES

Barbiturates are effective as anxiolytics, hypnotics, and anticonvulsants but have physical and psychological addiction potential as well as overdose potential among other possible adverse effects. They have largely been replaced by benzodiazepines and nonbenzodiazepines ("Z-drugs") in routine medical practice, particularly in the treatment of anxiety and insomnia, due to the significantly lower risk of addiction and overdose and the lack of an antidote for barbiturate overdose. Despite this, barbiturates are still in use for various purposes: in general, anesthesia, epilepsy, treatment of acute migraines or cluster headaches, acute tension headaches, euthanasia, capital punishment, and assisted suicide. Phenobarbital has extensive use as an antiepileptic drug in the neonatal and pediatric population (**Flowchart 1**). It is the most cost-effective drug treatment for epilepsy in adults in low-resource countries. Intravenous barbiturates have been used for neurosurgery due to the reduction in cerebral metabolic rate of oxygen consumption. For individuals with severe traumatic brain injury (TBI), high-dose barbiturates may be a consideration but are not indicated for prophylactic administration. In a review of practice in five European countries, about 20% of patients received barbiturates. In the treatment of refractory status epilepticus, a Cochrane review found that thiopental was equally effective as propofol for control of seizure activity.



FLOWCHART 1: Pharmacological classification based on the duration of action of barbiturates.

Thiopental was introduced in 1934 for induction of anesthesia for general anesthesia. Thiopental was the predominant intravenous (IV) anesthetic induction agent until its replacement by propofol. Because of its use in lethal injection protocols, the major supplier of thiopental elected to discontinue production in 2011.

Methohexital has demonstrated safety and effectiveness for procedural sedation of short duration for cardioversion, pediatric outpatient surgery, emergency department fracture reduction, and sedation for elective intubation in neonates. Methohexital has preferential use in electroconvulsive therapy due to its longer seizure duration. Phenobarbital has frequent use in the pediatric population; half-lives range between 59 and 182 hours. Both methohexital and thiopental may be administered rectally in pediatric, particularly if the child is unable to cooperate in IV needle insertion.

Epidemiology

Acute barbiturate toxicity may occur as the result of an intentional or unintentional overdose. Barbiturates have a history of abuse; the Health Department data showed 8,469 cases of barbiturate poisoning in the period between 1957 and 1963.

Pathophysiology

Phenobarbital is known to be an inducer of the cytochrome enzyme system, specifically the 1A2, 2B6, 2C9, and 3A4/5 isozymes, that will reduce the efficacy of warfarin, steroids, oral contraceptives, psychoactive, and immunosuppressants. Phenobarbital will also lower the plasma concentrations of other antiepileptic drugs such as lamotrigine, oxcarbazepine, phenytoin, tiagabine, and valproate. Thiopental and thiamylal have been shown to release histamine, while methohexital and pentobarbital have minimal histamine release.

Clinical Features

Overdosage of phenobarbital symptoms includes central nervous system (CNS) depression, respiratory failure, and hemodynamic instability. Extravasation of thiopental (a vesicant) may cause severe tissue necrosis.

Diagnosis

Phenobarbital has a narrow therapeutic range of 10–30 mg/L, with 80 mg/L reported as being fatal. A Cochrane review found no clear evidence of a benefit to routine serum monitoring of drug levels for antiepileptic drugs. Dose titration to control seizures was found to be effective.

Treatment

No antidote available for barbiturate overdose. Treatment of an overdose includes supportive care, activated charcoal, and urinary alkalinization (**Flowchart 2**). If extravasation of thiopental occurs, treatment measures include hyaluronidase and phentolamine.

PHENYTOIN TOXICITY

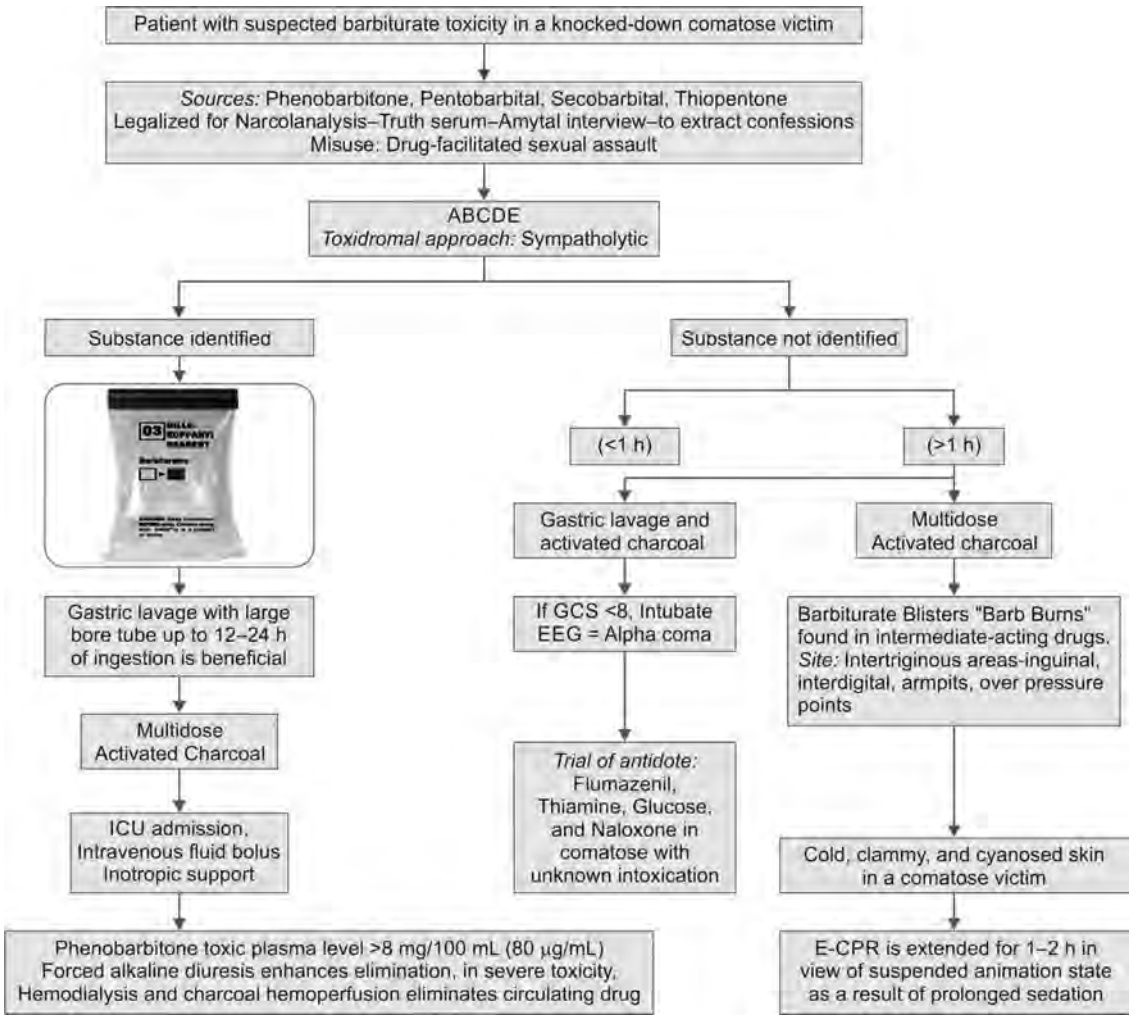
Since its discovery in 1908, phenytoin has become one of the well-studied anticonvulsants. It has also become one of the most widely used anticonvulsants, listed on the World Health Organization's List of Essential Medicines. It has a narrow therapeutic index and it is used daily, considering that potential phenytoin overdose or toxicity from chronic use is vital to early management and prevention of its further toxicity.

Epidemiology

According to the Annual Report of the American Association of Poison Control Centers (AAPCC) National Poison Data System 1971, single-substance phenytoin exposures resulted in 46 major outcomes and 1 death.

Pathophysiology

As in other toxicologic overdoses, the character of the toxicity depends on basic pharmacologic pathophysiology: the route of exposure (oral vs. parenteral), duration of exposure (acute overdose vs. chronic), and dosage, and therefore the nature of metabolism (or deficiency thereof). Phenytoin displays its main signs of toxicity on the nervous and cardiovascular systems. Overdose of oral phenytoin mainly causes neurotoxicity and very rarely causes cardiovascular toxicity. On the other hand, cardiovascular toxicity is the main side effect of parenteral administration.



Patient with suspected barbiturate toxicity in a knocked-down comatose victim
Sources: Phenobarbitone, Pentobarbital, Secobarbital, Thiopentone
Legalized for Narcolanalysis–Truth serum–Amytal interview–to extract confessions
Misuse: Drug-facilitated sexual assault
ABCDE
Toxidromal approach: Sympatholytic
Substance identified
Substance not identified
(<1 h)
(>1 h)
Gastric lavage and activated charcoal
Multidose Activated charcoal
Gastric lavage with large bore tube up to 12–24 h of ingestion is beneficial
If GCS <8, Intubate
EEG = Alpha coma
Barbiturate Blisters "Barb Burns" found in intermediate-acting drugs.
Site: Intertriginous areas-inguinal, interdigital, armpits, over pressure points
Multidose Activated Charcoal
Trial of antidote: Flumazenil, Thiamine, Glucose, and Naloxone in comatose with unknown intoxication
ICU admission, Intravenous fluid bolus Inotropic support
Cold, clammy, and cyanosed skin in a comatose victim
Phenobarbitone toxic plasma level >8 mg/100 mL (80 µg/mL)
Forced alkaline diuresis enhances elimination, in severe toxicity.
Hemodialysis and charcoal hemoperfusion eliminates circulating drug
E-CPR is extended for 1–2 h in view of suspended animation state as a result of prolonged sedation

(E-CPR: extracorporeal cardiopulmonary resuscitation; EEG: electroencephalogram; GCS: Glasgow Coma Scale; ICU: intensive care unit)

FLOWCHART 2: Algorithm for managing barbiturate toxicity.

Note: The Dille–Koppanyi reagent turns phenobarbitone, pentobarbital, amobarbital, and secobarbital into light purple.

Clinical Features

Neurotoxicity

The neurotoxic effects are dependent on plasma concentration and may range from mild nystagmus to ataxia, slurred speech, vomiting, lethargy, and eventually coma and death. Paradoxically, at very high concentrations, phenytoin can cause seizures. Symptoms correlate well with the unbound plasma phenytoin concentration. However, this laboratory value is seldom obtained. The following is a loose correlation of side effects with total plasma phenytoin concentrations (the value obtained in most laboratories):

- <10 mg/L: Rare side effects
- 10–20 mg/L: Occasional mild horizontal nystagmus on lateral gaze
- 20–30 mg/L: Nystagmus
- 30–40 mg/L: Ataxia, slurred speech, tremor, nausea, vomiting
- 40–50 mg/L: Lethargy, confusion, hyperactivity
- >50 mg/L: Coma and seizures

Seizures are very rare and usually occur at very high serum concentrations. The presence of seizures in a patient with suspected phenytoin toxicity due to overdose should prompt the search for other ingested toxins or drugs of abuse.

Cardiac Toxicity

Phenytoin is a class IB antiarrhythmic drug, although it is no longer used as an antiarrhythmic by cardiologists. Its effects on the heart's voltage-gated sodium (Na^+) channels can lead to arrhythmias as well as sinoatrial and atrioventricular nodal blocks, although such effects have rarely been reported following ingestion of the oral form. In the intravenous form, the main toxicity is believed to be from its parenteral vehicle—propylene glycol. Propylene glycol is a cardiac depressant and rapid infusions can lead to bradycardia, hypotension, and asystole. Care must be taken so that phenytoin is not administered intravenously at a rate >50 mg/min.

Other Toxicities

"Purple glove syndrome" is an adverse effect that can occur with phenytoin intravenously. It presents with discoloration and worsened edema of distal limbs, which can lead to extensive skin necrosis and limb ischemia. Phenytoin hypersensitivity has also been reported, generally occurring 1 week to 1 month after initiation of therapy. It presents with a raised temperature and skin rash and rarely leads to hepatitis, myocarditis, and pneumonitis.

Phenytoin has suicidal tendency as its adverse effect, but oral phenytoin–related toxicity is rarely fatal. Injectable phenytoin-related toxicity is mainly due to its fast infusion. Extracorporeal therapy such as dialysis is not routinely indicated to remove phenytoin in acute overdose.

As the mortality associated with phenytoin is very small, the primary indication of extracorporeal toxin removal (ECTR) is to reduce morbidity associated with prolonged incapacitating ataxia due to chronic phenytoin toxicity. However, ECTR should not be initiated solely based on a suspected dose of phenytoin ingested or serum phenytoin level.

The EXTRIP (Extracorporeal Treatments in Poisoning) group recommends ECTR to remove phenytoin by hemoperfusion and therapeutic plasma exchange. ECTR is not routinely indicated but in selected patients [chronic kidney disease (CKD) with kidney dysfunction and hypoalbuminemia, which reduce protein binding] with severe toxicity of chronic phenytoin overdose, with prolonged incapacitating ataxia, charcoal hemoperfusion may be helpful in selected patients. Historically, intermittent hemodialysis (IHD) has not shown to be effective in the removal of phenytoin, but with the use of modern high-efficiency filters, especially in the presence of conditions such as kidney dysfunction and hypoalbuminemia (in these selected patients, which reduce protein binding), IHD with albumin supplemented dialysate during modeled continuous hemodialysis may be effective.

Diagnosis

All patients suspected of possible phenytoin overdose should be evaluated with a broad differential in mind. Blood glucose level should be obtained in all patient. An ECG is suggested on all suspected phenytoin overdose patients, especially patients who have received parenteral phenytoin.

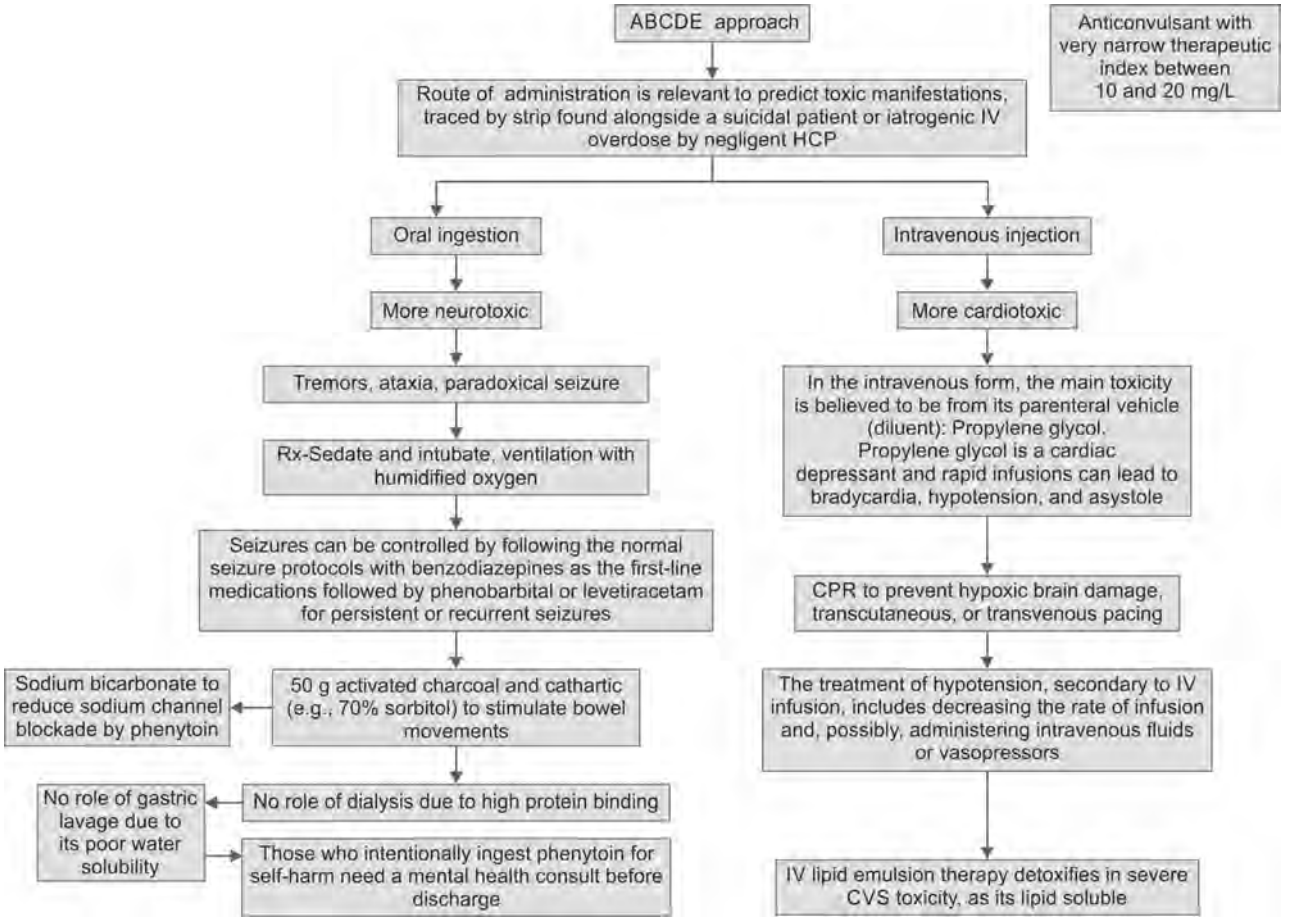
Laboratory work should be obtained including a complete blood count (CBC), basic metabolic panel (BMP), liver function test (LFT), total serum phenytoin concentration, and serum albumin. Urine toxicology, as well as acetaminophen, salicylic acid, and alcohol levels, should also be obtained to complete the toxicological workup. A serum phenytoin level at 10–20 mg/L has a narrow therapeutic window. Serum concentrations of phenytoin are monitored by measuring the total phenytoin concentration. However, phenytoin is generally 90% bound to plasma proteins (mostly albumin), and only its unbound form is pharmacologically active.

Treatment

No specific antidote is available, and the treatment is largely supportive care (**Flowchart 3**). The management of phenytoin toxicity should initially proceed along the lines of the Indian Society of Toxicology Life support (ISTOLS) guidelines of accepted treatment of toxic overdoses. The airway should be assessed, and advanced airway management should be initiated in patients who cannot maintain their airway or respiratory drive. The circulation should be assessed and abnormalities in vital signs addressed. Hypotension can be treated with an initial bolus of isotonic solution. If unresponsive to fluid administration, vasopressors can be initiated with norepinephrine or dopamine being preferred. Bradycardia can also be managed according to standard ISTOLS protocols including atropine, epinephrine and, if needed, transcutaneous or transvenous pacing. Consultation with a medical toxicologist is highly recommended.

Activated charcoal reliably binds phenytoin and prevents absorption. In acute ingestions, one dose of activated charcoal may be of benefit, especially in large acute overdoses, as phenytoin slows gastrointestinal (GI) motility and absorption is delayed. Activated charcoal is also of benefit in acute ingestions of extended-release tablets. Activated charcoal is not recommended if there is a depressed mental state. The role of multidose activated charcoal is controversial. Some studies have shown increased clearance rates although no clinical benefit or improvement in patient outcomes could be demonstrated. Induced emesis, gastric lavage, and whole bowel irrigation are not recommended for phenytoin overdose.

Despite high-plasma protein binding by phenytoin, the drug can be removed by hemodialysis with moderate effectiveness. However, clinical benefits are controversial.



ABCDE approach
Anticonvulsant with very narrow therapeutic index between 10 and 20 mg/L
Route of administration is relevant to predict toxic manifestations, traced by strip found alongside a suicidal patient or iatrogenic IV overdose by negligent HCP
Oral ingestion
Intravenous injection
More neurotoxic
More cardiotoxic
Tremors, ataxia, paradoxical seizure
In the intravenous form, the main toxicity is believed to be from its parenteral vehicle (diluent): Propylene glycol. Propylene glycol is a cardiac depressant and rapid infusions can lead to bradycardia, hypotension, and asystole
Rx-Sedate and intubate, ventilation with humidified oxygen
Seizures can be controlled by following the normal seizure protocols with benzodiazepines as the first-line medications followed by phenobarbital or levetiracetam for persistent or recurrent seizures
CPR to prevent hypoxic brain damage, transcutaneous, or transvenous pacing
Sodium bicarbonate to reduce sodium channel blockade by phenytoin
50 g activated charcoal and cathartic (e.g., 70% sorbitol) to stimulate bowel movements
The treatment of hypotension, secondary to IV infusion, includes decreasing the rate of infusion and, possibly, administering intravenous fluids or vasopressors
No role of gastric lavage due to its poor water solubility
No role of dialysis due to high protein binding
Those who intentionally ingest phenytoin for self-harm need a mental health consult before discharge
IV lipid emulsion therapy detoxifies in severe CVS toxicity, as its lipid soluble

(CPR: cardiopulmonary resuscitation; CVS: cardiovascular; HCP: health care professional; IV: intravenous)

FLOWCHART 3: Algorithm for managing phenytoin overdose and toxicity.

Due to the high-risk nature of hemodialysis, the effectiveness of supportive treatment, and the self-limited nature of acute overdoses, hemodialysis is rarely recommended and should only be used in extreme situations after consultation with a medical toxicologist.

The key to phenytoin toxicity is prevention, which is best done by an interprofessional team. Both the nurse and the pharmacist should educate the patient on the dangers of a drug overdose and the importance of not changing the dose. Those who intentionally ingest phenytoin for self-harm need mental health consult prior to discharge. If the older patient has difficulty reading the label on the vial or not capable of maintaining good hydration while on phenytoin, social work should be involved. In addition, the pharmacist should ensure that there is no polypharmacy and the risk of drug interactions is minimal.

204
CHAPTER

Sedatives Benzodiazepine and Nonbenzodiazepine

Chidrupi Sharma

INTRODUCTION

A sedative is a drug that reduces excitement, anxiety, and responsiveness to any form of stimulation and produces a calming effect on the patient. A sedative drug produces its effect in the form of anxiolysis, hypnosis, amnesia, and sedation, as an anticonvulsant and muscle relaxation. In this chapter, benzodiazepine (BZD) and nonbenzodiazepine sedatives are discussed.

BENZODIAZEPINES

Benzodiazepines are commonly used orally or parenterally. In the emergency department, IV doses are used for seizure control, procedural sedation, and acute psychosis. Oral doses are recommended for anxiety, nervousness, panic disorders, muscle spasms, insomnia, alcohol withdrawal, premenstrual syndrome, etc. (**Table 1**). BZDs when parenterally used, especially in combination with opioids or other sedatives, may cause respiratory depression and hypotension. Parenteral administration of these drugs is always done under the supervision of doctors trained in advanced airway management. BZDs can be classified as short, intermediate, and long-acting BZDs.

- *Short-acting drugs*: Midazolam, alprazolam, oxazepam
- *Intermediate-acting drugs*: Lorazepam, nitrazepam, flunitrazepam
- *Long-acting drugs*: Diazepam, clonazepam, chlordiazepoxide, flurazepam

TABLE 1: Uses of benzodiazepines.

Condition	*Commonly used drugs*
Anxiety disorder	Alprazolam, chlordiazepoxide, clorazepate, diazepam, lorazepam, midazolam
Seizure disorders	Clonazepam, clorazepate, lorazepam, clobazam, diazepam
Insomnia	Estazolam, flurazepam, quazepam, temazepam, triazolam
Procedural sedation	Midazolam, lorazepam
Muscle relaxation	Diazepam
Alcohol withdrawal	Chlordiazepoxide

Mechanism of Action

Benzodiazepines work on the midbrain ascending reticular formation, on limbic systems leading to sedation and anxiolysis, and on the medulla for muscle relaxation. These drugs act by stimulating the α subunit of the γ-aminobutyric acid (GABA) receptors in the central nervous system (CNS), thereby reducing their excitability throughout the CNS, producing sedation, anxiolysis, anticonvulsant effect, and muscle relaxation. These drugs are lipid-soluble. The more the lipophilic nature of the drug, the faster the onset of its action but shorter its duration of activity. The drugs rapidly move into the tissue storage sites such as liver and fat/adipose tissue. Hence, serum levels are not an accurate indicator of the true levels of the drug to assess the duration of action of the drugs. Routes of administration are IM, IV, intranasal, and transbuccal.

Adverse Effects

Benzodiazepines are relatively safe to use. Toxicity is usually seen when used along with other drugs like opioids. Prolonged usage may cause dependence, especially noticed with alprazolam. Abrupt stoppage of the drug can lead to "withdrawal syndrome" which presents with anxiety, insomnia, anorexia, disorientation, confusion, irritability, sleep disorders, delirium, psychosis, and even seizures. Withdrawal may be seen as long as a week after stoppage of the drug. This withdrawal is treated with long-acting BZDs such as clonazepam or other antiepileptic drugs, such as sodium valproate and carbamazepine. Tapering the drug dose gradually is recommended to avoid withdrawal symptoms. Overdose/toxicity is mostly neurological, seen as somnolence, dizziness, ataxia, vertigo, and confusion. Coma as a presentation is seen in combination with other sedative-hypnotic agents. Unusual adverse effects, such as extrapyramidal syndrome and allergic reactions, are very rare.

Benzodiazepine Toxicity

A patient presents with dizziness, confusion, drowsiness, and unresponsiveness/agitation. On examination, there is altered mental status, slurred speech, hypotonia, respiratory depression, ataxia, nystagmus, hypotension, paradoxical agitation, or coma. Differential diagnoses with other sedative-hypnotic drug overdoses, alcohol toxicity, hypoglycemia, stroke, etc., should be kept in mind while examining and planning treatment.

History and clinical examination are the best diagnostic tools for identifying BZD overdose. The patient or the attendants should be asked the time since ingestion, amount consumed, other medications or alcohol consumption along with BZD, history of mental and psychological status, pregnancy status for women in the reproductive age group, any treatment given at home to induce emesis, other comorbid conditions, medications, if any, being used by the patient, etc. Any medication strips seen near the patient or on the scene should be asked to be brought in, as this will help in estimating the dose and the drugs consumed and plan treatment with antidotes and other supportive case and aid in prognosticating the patient's outcome. Examine the patient for injuries, either due to physical abuse or due to self-infliction. A history of accidental or intentional overdosing should be obtained.

Diagnosis

Needlestick glucose levels are done to rule out possible hypoglycemia. Blood, urine, and gastric lavage samples should be sent for toxicological immunoassay screening. Only BZDs that metabolize into desmethyldiazepam or oxazepam are detected in these screening tests, thus leaving a large gray area of undetected BZDs that are not metabolized but maybe present. These are usually performed for medicolegal purposes and the results are not useful in an acute setting. Perform arterial blood gas (ABG) analysis to check for CO_2 narcosis and respiratory acidosis and electrocardiogram (ECG) to check for QT prolongation, tall T waves, and associated drug toxicity, such as tricyclic antidepressants (TCAs). A urine pregnancy test is recommended in all women in reproductive age groups. Renal profile, liver profile, and blood alcohol level examination should be routinely done. A CT scan of the brain is done when there is a strong suspicion of trauma or stroke as a differential for the clinical condition.

Treatment

Airway

In severe toxicity, the patient is very drowsy and can have a threatened airway. Monitor the patient's condition clinically for a compromised airway. Elective intubation with mechanical ventilation should be done as indicated.

Breathing

Respiratory depression leading to hypoxia and hypercarbia can be observed. Supplemental oxygen should be provided. Blood gas analysis should be done repeatedly to guide treatment. Altered mental status and coma can cause aspiration pneumonia. This should be borne in mind before inducing emesis or administering any substance orally or through Ryle's tube.

Circulation

Hypotension is an observed side effect with BZD overdose. Obtain a large-bore IV access. Fluid resuscitation and, if needed, ionotropic support should be provided.

Disability

Systematic repetitive neurologic assessment should be done throughout the stay in the emergency department (ED) and later on to check the effect of treatment on the neurological status. Other clinical conditions mimicking poor neurological status such as stroke, severe head injury, and other conditions leading to raised intracranial pressure (ICP) should be parallelly thought of while assessing a patient with suspected BZD and sedative toxicity.

General Measures

Ryle's tube placement provides access to initiate gastric lavage. Lavage is best effective, especially when done within 1 hour of ingestion of most of the drugs. Activated charcoal is debatably used as poor mentation can make the patient aspirate the gastric contents. Other drug elimination methods, such as hemodialysis and forced diuresis, are not effective. Naloxone can be tried when there is a suspicion of opioid toxicity as a cause for respiratory depression.

Benzodiazepine Antagonist

Flumazenil is a BZD analog having a selective antagonistic effect on BZDs when used in overdose. It antagonizes and abolishes the hypnogenic, psychomotor, and cognitive actions of BZD toxicity. It is commonly used for reversal of coma leading to respiratory depression and anesthesia caused by BZDs during procedural sedation. Flumazenil should be used with caution in cases where there is no clear history of BZDs as a cause of the current clinical condition. Some of the contraindications for flumazenil administration are as follows:

- Overdose with unknown drugs or coingestion of other seizure-inducing drugs
- Chronic BZD use
- Suspected TCA overdose
- Known seizure disorder
- Conditions causing raised ICP such as stroke and head trauma

Flumazenil has high first-pass metabolism and hence is administered intravenously. *Dosage*: It is available as a 1-mg ampoule. IV dose is 0.2 mg repeated to a maximum of 3 mg, repeated every minute and based on the patient's response. Seizures are a side effect of flumazenil administration, especially when there are co-ingestion and toxicity with TCAs. Flumazenil-induced seizures should be treated with phenobarbital or propofol.

Disposition

Admission is warranted for those patients exhibiting signs of severe respiratory depression, hypotension, or significantly altered mental status. Supportive care with effective management of airway, breathing, and circulation (ABC),

administration of antidote, and close monitoring for worsening or improvement of symptoms is done in the ED. Other differentials are worked on and those patients who are still symptomatic or who do not show much improvement are admitted to the intensive care unit.

NONBENZODIAZEPINES

Nonbenzodiazepines are predominantly used in the treatment of acute and chronic insomnia. Described here are four drugs called the "Z drugs:" (1) zolpidem, (2) zopiclone, (3) zaleplon, (4) eszopiclone. The details of the pharmacology of the drug are given in **Table 2**. All Z drugs are only used for the short-term use of insomnia which should last for days to a maximum of 4 weeks.

Zolpidem

Zolpidem is the most commonly used nonbenzodiazepine drug. It is available as tablets for immediate release, extended release, and sublingual use and as an oral spray prescribed specifically for different types of sleep disorders such as difficulty in sleep onset and maintenance or middle of night awakening. Caution should be exercised while prescribing zolpidem and other GABA agonists in this class, for patients with hepatic impairment (precipitates hepatic encephalopathy), chronic obstructive pulmonary disease (COPD), and sleep apnea. Toxicity or overdose presents as dizziness, headache, prolonged reaction time, reduced alertness, drowsiness, hallucinations, etc., "complex sleep behaviors" including sleep-walking, sleep-driving, falls, etc., can lead to very harmful injuries or death, especially in industry workers and drivers. Medications should be stopped immediately if the patient experiences complications. Peak plasma concentrations: 1.6 hours (immediate release), 1.5 hours (extended release), 0.9 hours (spray), 0.6–1.4 hours (sublingual). Elimination half-life is prolonged by about four times in hepatic impairment.

Zaleplon

Zaleplon is a GABA-BZD receptor complex agonist with a duration of action shorter than zolpidem. It is available as 5- and 10-mg capsules and used for short-term insomnia. It should be used cautiously in hepatic impairment. Headache is seen as a common side effect which is treated symptomatically and warrants dose adjustment. It is shown to cause serious complications when used with alcohol, fentanyl, and hydrocodone, and concomitant use is not recommended. Among the Z drugs, zaleplon causes the least adverse effects and withdrawal may be because of its short half-life.

Eszopiclone

Though its mechanism of actions is not clearly known, it is the active isomer of zopiclone. The dosage is available orally as 1-, 2-, and 3-mg tablets. The drug is rapidly absorbed and metabolized in the liver. About 50% of the drug is excreted by decarboxylation from the lungs. Adverse effects are poor coordination, headache, complex sleep disorder, and unpleasant taste, especially seen in the younger population.

Other nonbenzodiazepines such as buspirone, chloral hydrate, γ-hydroxybutyrate, meprobamate, melatonin, and its receptor agonists such as ramelteon and tasimelteon are also some categories of drugs used to treat insomnia.

Overdose/Toxicity

Overdose/toxicity presents as dizziness, CNS depression, drowsiness, coma, confusion, and respiratory depression. Treatment is supportive care with the management of ABCD (airway, breathing, circulation, and disability). Consider activated charcoal at 1 g/kg body weight, if the patient presents within 1 hour of ingestion of the drug. No specific antidote is available for nonbenzodiazepine overdose.

SUMMARY

Nonbenzodiazepine drugs have been shown to have lesser side effects and are more selective than the older benzodiazepine anxiolytic drugs. They produce effective anxiolysis with little or no sedation, anterograde amnesia, or anticonvulsant effects. Dependency and withdrawal syndrome are less with nonbenzodiazepines.

TABLE 2: Nonbenzodiazepine sedatives.

Name	*Time to peak plasma level*	*Oral bio-availability*	*Elimination half-life*	*Dose*	*Time for drug administering before sleep*
Zolpidem	1–2 h	65–70%	1.4–4.5 h	• 5-, 10-mg tablets • 6.25-, 12.5-mg extended-release tablets • 1.75-, 3.5-, 5-, 10-mg sublingual tablets • 5-mg nasal spray called zolpimist	• Immediately before bedtime with 7–8 h before waking • 1.75-mg sublingual tablet to be taken >4 h of sleep remaining in conditions of middle of night awakening
Zopiclone	1.5– 2 h	75–80%	5–6 h	3.75-, 7.5-mg film-coated tablets	Immediately before bedtime with 7–8 h before waking
Zaleplon	0.7–1.4 h	30%	0.9–1.2 h	5-, 10-mg capsules	Immediately before bedtime with 7–8 h before waking
Eszopiclone	1–1.5 h	75–80%	6–7 h	1-, 2-, 3-mg tablets	Immediately before bedtime with 7–8 h before waking

205
CHAPTER

Opioids

Olita Shilpakar

INTRODUCTION

Opioid is a term designated for a number of natural substances, originally derived from opium (Greek word: juice of poppy plant, *Papaver somniferum*), and their analogs that bind to specific opioid receptors. *Opiates* are compounds derived from the opioid alkaloids found naturally in the opium poppy plant. Opioids are among one of the widely used drugs since ancient times for sedation and analgesia. In the past few years, opioid abuse is becoming a significant public health issue all over the world resulting in increase of cases of opioid toxicity and opioid overdose deaths.*Opioids are categorized into three forms,* namely (1) naturally occurring compounds (opiates), (2) chemically modified natural compounds (semisynthetic), and (3) completely artificial compounds (synthetic) (**Table 1**). Opioids may act as agonists at all opioid receptors (e.g., morphine and hydromorphone), agonists–antagonists (e.g., pentazocine, butorphanol, nalbuphine) at the opioid receptors and some as antagonists (e.g., naloxone) (**Table 2**).

PATHOPHYSIOLOGY

Opioids act on three major classes of *opioid receptors* which are G protein-coupled transmembrane molecules: μ (mu), κ (kappa), and δ (delta). Stimulation of the μ-receptors results in analgesia, respiratory depression, sedation, miosis, bradycardia, cough suppression, gastrointestinal dysmotility, and euphoria. The κ-receptor stimulation can yield a weaker analgesia, sedation, hallucinations, miosis, and dysphoria whereas the δ-receptors show mood modulation effects along with pain control.

Opioid receptors are distributed throughout the body. Nociception is mediated by the thalamus, amygdala, and the dorsal-root ganglia. Respiratory depression is caused by brain stem opioid receptors along with the dopaminergic neurons which modulate the responses to hypercarbia and hypoxic drive. Stimulation of opioid receptors in the Edinger–Westphal nucleus of the oculomotor nerve controls the pupillary constriction causing miosis. The receptors in the gastrointestinal tract decrease gut motility.

TABLE 1: Categorization and characteristics of opioids.

Types of opioid	*Duration of action (hours)*	*Elimination half-life (hours)*
Opiate		
Codeine	4–6	2.5–4
Morphine	3–4	2–4
Semisynthetic		
Buprenorphine	6–24	20–44
Hydrocodone	4–6	8
Hydromorphone	2–4	2–3
Oxycodone	3–6	3–4
Synthetic		
Fentanyl	1	3–4
Methadone	4–8	12–18
Meperidine	1–3	3–4
Pentazocine	3–4	2–4
Propoxyphene	4–6	6–12
Tramadol	4–6	5–7

TABLE 2: Classification of opioid agonists and antagonists.

Agonists	*Agonist–antagonists*	*Antagonists*
Morphine	Pentazocine	Naloxone
Meperidine	Buprenorphine	Naltrexone
Methadone	Butorphanol	Nalmefene
Hydromorphone	Nalbuphine	
Heroin	Nalorphine	
Fentanyl		
Tramadol		

TOXICOKINETICS

Opiates have a wide diversity of routes of administration, namely intravenous, intramuscular, oral, subcutaneous, buccal, topical, and inhalational routes. When ingested orally, opioids are readily absorbed, achieving peak blood levels within 30–60 minutes following ingestion and up to 90 minutes in sustained-release formulations. Opioid absorption occurs in the small intestine following which they undergo hepatic first-pass metabolism and renal elimination. Different opioids can cross the blood–brain barrier differently due to variability in their lipid solubility. Following nasal insufflation of heroin, peak levels are achieved within 10–15 minutes while intramuscular injection takes about 30–45 minutes and fentanyl patches around 2–4 hours to reach peak levels. In cases of drug overdose, there is alteration in the pharmacokinetics which may increase the severity and duration of action beyond the therapeutic range.

CLINICAL EVALUATION

Clinical Presentation

The classical triad of opioid toxidrome includes respiratory depression, central nervous system depression (CNS), and miosis. These findings may not be consistently present in all the cases and the diagnosis is therefore based on a reliable history and thorough clinical examination.

History

A pertinent history is obtained from family, friends, bystanders, and emergency medical service providers since majority of patients are lethargic or comatose due to opioid overdose. One may find pills, bottles, needles, syringes, and drug paraphernalia. Detailed history regarding the type and quantity of drug ingested and time of ingestion should be ascertained.

Physical Examination

Opioid toxicity characteristically presents with respiratory depression, mental state depression, and pupillary miosis which are considered the hallmarks of the toxidrome. It may encompass with a wide range of clinical findings.

Pulmonary

The most readily recognized abnormality is a decline in the respiratory rate characterized by slow and shallow respirations resulting in hypoxia, hypercarbia, and cyanosis. Morphine overdose may be observed as shallow breathing, hypopnea, bradypnea with a respiratory rate of <12 breaths/min and occasionally with bronchoconstriction presenting with dyspnea, wheezing, and pink frothy sputum.Opioid-induced acute lung injury, previously known as noncardiogenic pulmonary edema, is an infrequent complication of heroin overdose and occurs immediately or up to 24 hours after the ingestion. The pathophysiology of acute lung injury in opioid overdose may be related to a capillary leak phenomenon. Opioid-induced ventilatory impairment (OIVI) is a more complete term comprising opioid-induced central respiratory depression (decreased respiratory drive), decreased level of consciousness (sedation), and upper airway obstruction. All of these may result in decreased alveolar ventilation and increased arterial carbon dioxide levels.

Neurological

Mental state depression is frequently encountered with high doses of opioids. Generalized seizures have been reported in adults, mostly following propoxyphene or meperidine ingestion since opioids can lower the seizure threshold.Young children are also at risk primarily due to paradoxical excitation of the CNS. Neuropsychiatric symptoms such as anxiety, agitation, hallucinations, euphoria, paranoia, and dysphoria may be noted with higher doses. Serotonin syndrome is caused by the combination of opioids such as meperidine and tramadol with selective serotonin reuptake inhibitors and monoamine oxidases and is characterized by hyperthermia, autonomic dysfunction, muscle rigidity, and hyperreflexia.

Eye

Miosis may be present in patients with opioid overdose. Frank mydriasis has also been reported secondary to morphine, meperidine, diphenoxylate, and propoxyphene toxicity along with respiratory depression and cerebral hypoxia.

Skin

Needle track marks in case of intravenous opiate abuse are observed. Morphine and heroin are injected illicitly by street users, subcutaneously known as "skin popping." Poor injection techniques could present with thrombophlebitis, cellulitis, aneurysms, intra-arterial injections, and embolization. Patch marks due to the use of transdermal fentanyl patches could also be observed. Opiates can cause the release of histamine resulting in pruritis, flushed skin, and urticaria.

Cardiovascular

Peripheral vasodilatation may result in orthostatic hypotension. In case of co-ingestion with other drugs, a severe form of refractory hypotension may occur. Ventricular arrhythmias have also been encountered at higher doses.

Gastrointestinal

Nausea, vomiting, decreased gastrointestinal motility, delayed gastric emptying, constipation, and ileus are seen in patients with opioid toxicity.

Others

Other findings include hypothermia, rhabdomyolysis, compartment syndrome, peripheral neuropathy, myoglobinuric renal failure, sensorineural hearing loss, and endocarditis. "Body stuffers" are patients who ingest loosely packaged bags of illicit drugs. Patients who ingest packaged packets of illicit drugs for trafficking purposes are known as "body packers." Heroin is a commonly used drug by both body stuffers and packers. As compared to stuffers, packers may have lethal amounts of drugs in a concentrated form and are at a higher risk of prolonged toxicity.

DIFFERENTIAL DIAGNOSIS

A list of both toxicological and nontoxicological differentials of opioid toxicity is given in **Table 3**.

TABLE 3: Differential diagnosis of opioid toxicity.	
Toxicological	***Nontoxicological***
Clonidine toxicity	Acute hypoglycemia
Benzodiazepine toxicity	Acute subdural hematoma
Barbiturate toxicity	Diabetic ketoacidosis
Sedative-hypnotic toxicity	Hyperosmolar hyperglycemic state
Organophosphate and carbamate toxicity	Meningitis
Cannabinoid toxicity	Pontine and intracerebral hemorrhage
Carbon monoxide toxicity	
Atypical antipsychotics toxicity	

INVESTIGATION

Clinical judgment is of utmost importance in case of opioid toxicity. Laboratory studies or drug screens may aid in the diagnosis but with limitations. A qualitative urine opioid screen can readily detect morphine and its naturally acting counterparts, such as codeine and heroin, which are metabolized to morphine. Positive results can be observed up to 36–48 hours postexposure. False-positive results have been reported in rifampin, diphenhydramine, dextromethorphan, ibuprofen, quetiapine, and fluoroquinolones, presumed to be due to interference with the immunoassay technique.

A chest radiograph should be obtained to evaluate for acute lung injury in case the patient presents with audible wheezes. If a "body packer" or a body stuffer" is suspected, abdominal X-rays might be helpful in making a diagnosis. A 12-lead electrocardiogram should be done to detect any possible cardiotoxicity, e.g., QRS widening or QTc prolongation, as seen in propoxyphene and methadone use.

TREATMENT

Stabilization and Supportive Care

Airway protection and ventilation are the most important measures that should be taken for the stabilization of the patient in the emergency department. Maintain adequate oxygenation and ventilation as required via a bag valve mask, bi-level positive airway pressure, continuous positive airway pressure, or rapid sequence endotracheal intubation and mechanical ventilation with positive end-expiratory pressure.

Decontamination

In case of ingestion of opioids preferably within an hour, oral activated charcoal can be administered at a dose of 1 g/kg body weight. Gastric lavage is not recommended because the risks outweigh the benefits. Whole bowel irrigation can be considered for body packers; however, close monitoring is required because of the high risk of rupture of the packets.

Enhanced Elimination

There are no clinically effective techniques for the enhanced elimination of opioids.

Antidote Therapy

Naloxone is a pure competitive opioid antagonist which has an affinity for μ receptors. It is an oxymorphone derivative which rapidly reverses the effects of opioid intoxication including respiratory depression, CNS depression, and miosis. Naloxone is not effective orally because its bioavailability is minimal but is well absorbed via intravenous, intramuscular, subcutaneous, inhalational, endotracheal, and intranasal routes. The onset of action of naloxone, when administered intravenously, is <2 minutes, the duration of action is between 20 minutes and 2 hours, and the elimination half-life is 60–90 minutes.

An initial dose of naloxone, 0.1–0.4 mg IV, is recommended in patients with CNS depression but with an adequate respiratory status. Subsequent small doses of naloxone of 0.1–0.4 mg IV are administered every 2–3 minutes and titrated until the desired effect is achieved since larger doses can precipitate opioid withdrawal symptoms. If the patient presents with severe respiratory depression, a bolus dose of naloxone, 2 mg IV, should be administered which should be followed by repeated doses of 2 mg IV every 3 minutes till the respiratory depression is reversed or till a maximum dose of 10 mg IV is reached.

In case the symptoms persist or worsen, a continuous naloxone infusion and an endotracheal intubation should be considered. A naloxone infusion dose is calculated as two-thirds of the dose that effectively reversed intoxication, also known as the "wake-up dose," and is administered per hour. Intramuscular, subcutaneous, or intranasal doses can be given as an initial dose of 2 mg and titrated accordingly. The same dose of naloxone is mixed with 3 mL of normal saline and can be used in the nebulized form. Other opioid antagonists are nalmefene and naltrexone which have a longer duration of action and half-lives than naloxone. However, naloxone still remains the antidote of choice for opioid reversal.

DISPOSITION

History and clinical examination are of utmost importance to determine the disposition of cases following opioid intoxication. Patients with opioid toxicity can be safely discharged within 4–6 hours after administration of naloxone if the patient is stable with a normal temperature, respiratory rate of >10 breaths/min, oxygen saturation of >92% in room air, and a Glasgow coma scale of 15. Longer acting or sustained-release opioids and moderate-to-severe overdose patients following multiple doses of antidote require intensive care admission. Psychiatric consultation and behavioral counseling are done prior to discharge of the patient.

OPIOID WITHDRAWAL

Opioid withdrawal occurs when opioids are stopped abruptly in a patient with physiological dependence or following the administration of an antagonist. It is a hyperadrenergic state with symptoms representing the reverse of opioid administration. The initial symptoms start within 6–12 hours of the last opioid use with anxiety, drug craving, yawning, lacrimation, diaphoresis, rhinorrhea, and myalgias which progress to nausea, vomiting, diarrhea, pain abdomen, piloerection, mydriasis, agitation, apprehension, hyperventilation, insomnia, and muscle spasms. These symptoms usually start

6–12 hours following abstinence, peak approximately by the third day, and abate by the fifth day.

Treatment of opioid withdrawal in the emergency room is symptomatic and consists of intravenous fluids and electrolyte replacement along with antiemetics. Administration of an alpha-2-agonist, clonidine, at a dose of 5 μg/kg orally, is known to shorten the withdrawal duration by suppressing the sympathetic hyperactivity. Methadone, a long-acting opioid, is used for maintenance therapy to prevent withdrawal and for treatment in de-addiction clinics.

SUMMARY

Opioids are among the oldest known drugs which refer to any natural, semisynthetic, or synthetic compounds having morphine-like properties. The hallmark of opioid toxidrome consists of respiratory depression, mental state depression, and miosis. The diagnosis is based on clinical evaluation. Management of opioid toxicity comprises airway protection, ventilation, and early administration of naloxone.

206
CHAPTER

Substance Abuse

Ramesh K Maharjan, Jukel Shrestha, Rashmisha Maharjan

HISTORY

Humans have a long history of substance abuse and have used substances for thousands of years. Early civilization used wine from at least the time of the early Egyptians. The earliest recorded use of narcotics dates back to 4000 BC with medicinal marijuana appearing in China around 2737 BC. The extraction of active ingredients from psychoactive substances did not occur until the 19th century.

Substance abuse is a worldwide problem that affects millions of people. It is mainly the young boys and girls who are engaging in drug use for a variety of reasons and many youngsters have already died from the drug use. Substance use poses serious challenges as it affects foremost the health and life of the substance user, then the social well-being of the family, and finally the whole community.

The use of drugs as part of the cultural norms did not create major social problems during traditional periods. However, the types of substance used have been shifted since the last few decades from *Cannabis* to synthetic opiates and chemical substances. Also, the mode of substance uses has changed from smoking/ingesting to injecting and that has become one of the major challenges for infectious diseases such as human immunodeficiency virus (HIV) and hepatitis infections. So, substance abuse has become a multidimensional problem and substance abuse treatment a challenge for the global world.

EPIDEMIOLOGY

In 2017, an estimated 271 million people, or 5.5% of the global population aged 15–64 years, had used substances in the previous year. While this is similar to the 2016 estimate, a longer term view reveals that the number of people who use substances is now higher than it was in 2009. Although that increase was in part due to a 10% growth in the global population aged 15–64 years, data now shows a higher prevalence of the use of opioids in Asia, Africa, Europe, and North America and the use of *Cannabis* in North America, South America, and Asia compared with 2009.

According to the survey, hard drug users have significantly increased in Asian countries. A very large majority of them happen to be young people. Most of the drug users started drug use very early, in fact before they reached 20 years. Only 50% of drug users were employed. *Cannabis* (90.5%), opiates (93.5%), tranquilizers (83.5%), inhalants (12.7%), hallucinogens (8.7%), and stimulants (5.2%) were the drugs used in descending order (**Table 1**). Injecting was again the main mode of drug administration. Peer pressure and curiosity were the main pulling factors for initiation of first-time drug use.

When it comes to tackling challenges inside the emergency room, a variety of stereotypes come to mind in compiling the profile of a substance abuser. Adherence to a belief in these stereotypes is a dangerous trap for the clinician. Physicians are likely to discount the possibility of substance intoxication in

TABLE 1: Commonly abused drugs.

Cannabis (marijuana) (90.5%)	Bhang, charas, ganja, sulfa
Opiates (93.5%)	• Heroin (Brown sugar, Smack, etc.) • Cough syrup (Corex, Phensedyl, etc.) • Pain medication • Propoxyphene (Darvon, Proxyvon) • Buprenorphine (Tidigesic) • Pethidine • Morphine • Pentazocine (Fortwin)
Tranquilizers (83.5%)	• Diazepam (Valium, Calmpose) • Nitrazepam (Nitravet, Dormin, Nitrosun) • Alprazolam (Alprax)
Inhalants (12.7%)	• Dendrite • Paint thinner • Varnish • Petrol
Hallucinogens (8.7%)	• LSD • Ketamine • Acid
Stimulants (sympathomimetic) (5.2%)	• Cocaine • Amphetamines

(LSD: lysergic acid diethylamide)

TABLE 2: Complications of illicit drug use.	
Neurologic	Strokes, SAH, seizures
Cardiac	Endocarditis, arrhythmias
Infectious	• HIV, hepatitis C, hepatitis B, infective endocarditis, STI's syphilis • Botulism, tetanus, osteomyelitis, septic joints • Abscess/cellulitis
Psychiatric	• Anxiety, depression, psychosis, suicide, panic attacks • Social isolation
Traumatic	Penetrating trauma, knife fights, blunt trauma, MVCs

(MVCs: motor vehicle collisions; SAH: subarachnoid hemorrhage; STI: sexually transmitted infection)

a well-dressed professional or in those at the extremes of age, but substance use and abuse span the spectrum of age, sex, economic, and intellectual status. Physicians have a difficult time recognizing such abuse, particularly in patients with chronic pain syndromes. In the emergency room, a patient with chronic pain may not manifest the typical overt sympathetic changes or physical findings of acute pain. Patients may seek treatment because of the perceived failure of their outpatient regimen, because of an acute flare-up, or because of abuse or addiction. Therefore, emergency clinicians constantly walk a tightrope between undertreating legitimate pain and inappropriately rewarding substance abusers with controlled medications.

In assessment and management planning, consider the primary toxic effect of the agent, complications of intoxication, and complications of the administration/injection technique. Complications of a poor injection technique include cellulitis, thrombophlebitis, intra-arterial injection and embolization, mycotic aneurysm, endocarditis, anaerobic infection, and blood-borne virus infection. So, a high index of suspicion is required. Presentation to an emergency department (ED) with acute intoxication or complications of drug use indicates an ongoing hazard and provides an opportunity for intervention (**Table 2**). Patients should be counseled regarding strategies to avoid future overdose and, if willing, should be referred to rehabilitation agencies. The drugs of misuse or abuse most commonly involved in deaths are cocaine, opioids, antidepressants, benzodiazepines, stimulants, and club drugs.

HALLUCINOGENS

Hallucinogens (psychedelics) cause alterations in perception. A hallucination is defined as a perception of an object or sensation that does not exist in reality. Hallucinogens may work by several different mechanisms, including stimulating the serotonergic 5-HT2A receptor, hyperactivation of the dopamine D2 receptor, and blockade of the glutamate *N*-methyl-d-aspartate (NMDA) receptors.

LYSERGAMIDES

Lysergic acid diethylamide (LSD), or acid, is a potent psychedelic drug. Doses of 1–1.5 μg/kg produce psychedelic effects. The typical dose taken for an acid trip is approximately 25–100 μg. LSD is sold as a tablet (microdot), liquid, powder, gelatin square (windowpane), and blotter acid. Sheets of blotting paper are sprayed with LSD, dried, and perforated into small squares. Each sheet is composed of hundreds of squares that are placed sublingually or eaten whole. Massive ingestions are rare.

LSD Blotters (Felix the Cat)

In terms of treatment of lysergamides, if panic attacks occur, proceed with nonpharmacologic and supportive care. Complications include harm to self/others. Look for rhabdomyolysis, seizures, and coagulopathy. Watch out for worsening depression postuse and sedate with benzodiazepam followed by second-line haloperidol for psychosis. Withdrawal symptoms are unknown. More research is needed to find out if behavioral therapies can be used to treat addiction to hallucinogens.

MARIJUANA AND SYNTHETIC CANNABINOIDS

Cannabis in South-East Asia has been used since as early as 2000 BC. In ancient Hindu society, common terms for *Cannabis* preparations include *charas* (resin), *ganja* (flower), and *bhang* (seeds and leaves). South-East Asian drinks, such as *bhang lassi*, are made from *bhang* which is one of the most common legal uses.

Cannabis sativa and *Cannabis indica* plants are some of the earliest plants grown by humans. Bioactive substances derived from these plants are collectively called cannabinoids. Marijuana is smoked, vaporized, or eaten blended into foods. Δ^9-Tetrahydrocannabinol (THC) is the main psychoactive agent of >61 cannabinoid compounds and approximately 300 other substances present in the *Cannabis* plant, and cannabidiol (CBD) is the major nonpsychoactive component. Cannabinoids act primarily at cannabinoid receptors CB1R, found mostly in the central nervous system (CNS), and CB2R, found primarily on peripheral immune cells. The discovery of these cannabinoid receptors and experiences in states with medical marijuana availability have led to an interest in further exploration of the therapeutic potential of cannabinoids.

Clinical Features

Smoking marijuana leads to rapid and predictable signs and symptoms. Ingestion can cause delayed and sometimes unpredictable effects. The most common effects of marijuana smoking include mood changes and typically relaxation and euphoria. A slight rise in heart rate and conjunctival injection are the only reliable physiologic results. Other acute peripheral changes include urinary retention, decreased testosterone levels, and decreased intraocular pressure. Short-term memory is impaired and the ability to perform complex tasks may be adversely affected. Many users report excessive appetite after marijuana use. Peak blood levels occur within 8 minutes of inhalation, with rapid distribution into tissues, especially tissues with a high lipid content. The duration of perceived effects is usually 2–4 hours when the drug is smoked.

Oral ingestion of marijuana edibles may be associated with a longer duration of effect (≥6–12 h), and patients with a

massive oral marijuana ingestion may develop profound ataxia, vomiting, agitation, anxiety, and CNS depression requiring medical care. Edible products often carry high concentrations of THC in relatively small portion sizes and, due to a delayed onset of effect up to 4 hours after ingestion, patients may ingest escalating amounts of the product while awaiting the onset of psychoactive effects.

Though intoxications with marijuana and synthetic cannabinoids may have some similarities, significant differences have been described. First-generation synthetic cannabinoids, such as JWH-018, JWH-073, HU-210, and CP-47, were commonly associated with tachycardia, agitation, nausea and vomiting, altered mentation, and hallucinations. Seizures were also noted with this group of cannabinoids. Second-generation synthetic cannabinoids, such as ADB-PINACA and AB-FUBINACA, have been associated with more profound agitation and aggression, seizures, tachycardia followed by bradycardia, and, less commonly, ischemic stroke and cardiac toxicity. Withdrawal symptoms of marijuana include irritability, trouble sleeping, decreased appetite, and anxiety.

Differential Diagnoses

The presentation that most closely resembles that of marijuana and synthetic cannabinoid intoxication is acute psychosis. Some individuals with underlying and preexisting psychiatric disorders may progress to overt psychosis after heavy or first-time marijuana use. Because marijuana is so readily available, it is commonly a cointoxicant used with ethanol and other psychotropic agents.

Diagnostic Testing

Marijuana screening is rarely helpful in the ED. Urinary metabolites of THC are detectable within 1 hour after smoking of marijuana, but a positive urine test result does not correlate with acute intoxication. A single marijuana cigarette can be detected for 72 hours when a cutoff level of 100 ng/mL is used, and positive urine levels may persist for 3 months after chronic marijuana use.

Management and Disposition

Care of patients intoxicated from marijuana and synthetic cannabinoids consists of prevention of injury and reassurance for those who have panic reactions. An extremely agitated patient can be sedated with oral or parenteral administration of benzodiazepines or antipsychotics. Antiemetics (e.g., ondansetron 4–8 mg IV or metoclopramide 10–20 mg IV) may be used to treat nausea and vomiting induced by the cannabinoid hyperemesis syndrome (CHS) associated with the synthetic cannabinoids and heavy, daily marijuana use. Hot showers are often recommended for patients suffering from these symptoms. The precise mechanism whereby hot bathing produces a rapid reduction in the symptoms of CHS is unknown. It has been postulated that hot water may act by correcting the cannabis-induced disequilibrium of the thermoregulatory system of the hypothalamus. Children who are significantly symptomatic may require admission for a 24-hour observation period. Behavioral therapies such as cognitive-behavioral therapy (CBT), contingency management, motivational incentives, motivational enhancement therapy can be used.

AMPHETAMINES

Pharmacology and Pathophysiology

The amphetamines as a class are based on a central structure of phenylethylamine that parallels that of the epinephrine, norepinephrine, and dopamine biogenic amines. Because of the resemblance, amphetamines may be presumed to specifically activate adrenergic receptors. Instead, they act to increase the number of adrenergic neurotransmitters that are released for any given stimulus. This results in higher levels of synaptic excitatory neurotransmission and the clinical effects which follow. Patients on amphetamines present on a spectrum from a mildly "energized" to a full-blown adrenergic crisis.

The central structure of amphetamine is suitable for substitution using very simple chemistry, and amphetamines such as 3,4-methylenedioxymethamphetamine (MDMA), methamphetamine, and "2-bromo-dragonfly" are available. These substances have been synthesized to take advantage of serotonin storage vesicles behavior for greater hallucinogen's "gain". A fairly well-known example is MDMA ("Ecstasy"). MDMA-intoxicated patients may present either as sympathomimetic, as serotonergic or, more likely, as a combination of both. Since these designer amphetamines have some degree of serotonergic activity, a core temperature is of critical importance; these substances can induce hyperthermia directly and interfere with other serotonergic medicines, and interactions with other serotonergic medications [e.g., selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs)] can precipitate serotonin syndrome. The street names of Methamphetamines are Crank, Chalk, Crystal, Fire, Glass, Go fast, Ice, Meth, Speed. Its commercial name is Desoxyn which is used to treat attention-deficit hyperactivity disorder. Its common forms include white powder or pill; crystal meth looks like pieces of glass or shiny blue-white "rocks" of different sizes.

Amphetamines are commonly taken via ingestion, smoking, inhalation, or injection. All are absorbed from the gastrointestinal (GI) system, with peak serum levels within 3 hours. They are weak bases, 20% bound to plasma proteins, and have large volumes of distribution. The half-lives vary between 8 and 30 hours. The main route of elimination is hepatic transformation; however, up to 30% of amphetamine and methamphetamine may be eliminated in the urine.

Amphetamines improve catecholamines release and inhibit their reuptake triggering increased central and peripheral adrenergic receptor activation contributing to sympathomimetic toxidrome. Higher doses bring about central release of serotonin. Substitutions alter the hallucinogenic, behavioral, and cardiovascular effects of the drugs. In overdose, the exact amphetamine may not be distinguishable as effects are more uniform.

Clinical Features

Central nervous system excitation and the peripheral sympathomimetic reaction are primary signs. Euphoria, apprehension, and agitation are common. The patient may present with tachypnoea, mydriasis, tremor, diaphoresis and hyperpyrexia, severe dental problems ("meth mouth"), and intense itching leading to skin sores from scratching. Psychosis can

occur with visual and tactile hallucinations, severe agitation, and paranoia resembling paranoid schizophrenia. Myocardial infarction, aortic dissection, rhabdomyolysis, acidosis, acute cardiomyopathy, shock, renal failure, and coagulopathy are documented. Symptoms may persist for several days. Death is secondary to hyperthermia, arrhythmia, intracerebral hemorrhage, or trauma.

After use of MDMA, hyponatremia with cerebral edema that presents as altered mental status and seizures is documented and can be fatal. Mechanisms that lead to hyponatremia include psychogenic polydipsia and insufficient antidiuretic hormone secretion.

Long-term abuse of amphetamines may be complicated by a necrotizing vasculitis which can involve multiple organ systems and proceed to renal failure, myocardial ischemia, and cerebrovascular disease.

Dependence and withdrawal of amphetamine are recognized. Withdrawal is characterized by neurasthenic symptoms, including somnolence and intense cravings for amphetamines, depression, anxiety, and tiredness. Management is supportive.

Differential Diagnosis

Amphetamine derivative overdose may not be clinically distinguishable from cocaine except for the elevated psychotic symptoms and a longer period of action. The differential diagnosis also includes anticholinergic delirium, serotonin syndrome, alcohol and benzodiazepine withdrawal, sepsis, thyrotoxicosis, and pheochromocytoma.

Clinical Investigations

Physical examination and investigations should be directed at excluding complications and alternative diagnoses. Seizures or coma should prompt investigation for complications, such as intracerebral hemorrhage or electrolyte disturbance. All patients should have a blood glucose measurement.

Treatment

Resuscitation prioritizing immediate life threats should be done. Treatment may be better in a quiet environment, away from unnecessary stimuli. Patients exhibiting psychomotor acceleration or psychosis should be managed with titrated intravenous sedation. Hyperthermia and seizure are important factors which contribute to morbidity and mortality. For effective treatment of hyperthermia and seizures, core temperature should be assessed in all patients and continuous monitoring is recommended if the temperature is elevated. Mild-to-moderate hyperthermia (<39°C) typically responds to benzodiazepine sedation and fluid resuscitation. If temperature continues to rise, intubation and paralysis are indicated. The use of dantrolene is not indicated. Benzodiazepines are first-line therapy for seizures, followed by barbiturates, and then general anesthesia. Seizures in the context of acute hyponatremia require initial rapid sodium replacement. Patients with persistent psychotic features may respond to an antipsychotic agent.

Disposition

The period of treatment in the ED and the need for admission would depend on the severity of intoxication, the effect of co-ingested medications, comorbidities, and complications. Patients with mild intoxication may be observed in the ED and discharged when vital signs and mental status have returned to the normal state. The long half-lives of the amphetamines may dictate inpatient care if symptoms or abnormal vital signs do not resolve within a few hours. Behavioral therapies such as CBT, contingency management, motivational incentives, the Matrix model, 12-step facilitation therapy, or mobile medical application: reSET® can be used.

COCAINE

Pharmacology and Pathophysiology

Cocaine hydrochloride, or benzoylmethylecgonine hydrochloride, is a powder extracted from the leaves of the coca plant Erythroxylon. "Freebase" cocaine is an alkaloid that is prepared by combining hydrochloride of cocaine, water, and baking soda and removing precipitates. If the solvent will evaporate, the crystals of pure cocaine, known as "rock" or "crack," remain. Cocaine reaches the cerebral circulation within seconds after smoking or insufflation. After oral ingestion, GI absorption may not peak for 90 minutes. Cocaine is hydrolyzed by plasma and liver cholinesterase to an active metabolite. About 5–10% of cocaine is excreted in the urine unchanged with a half-life of 60–90 minutes.

Common street names of cocaine are Blow, Bump, C, Coke, Crack, Dust, Flake, Nose candy, Rock, Snow, Sneeze, Toot, White Rock. The commercial name is Cocaine hydrochloride. Unpurified cocaine paste is converted to more usable forms of cocaine. The crystallized freebase of the cocaine alkaloid is known as *crack cocaine*. It is inhaled with the use of a special "crack pipe" designed to tolerate the high temperature required to volatilize pure cocaine. The high lipid solubility and rapid transport from the lungs into the brain contribute to crack's rapid onset of action. The water-soluble salts of cocaine (cocaine hydrochloride and cocaine sulfate) are available as a white crystalline powder that is used intranasally or dissolved and injected intravenously. Oral administration is rare except for patients who are smuggling or concealing drugs.

Cocaine is a CNS stimulant that works through enhanced noradrenaline release, plus noradrenaline, dopamine, and serotonin reuptake blockage. Dysphoria, hysteria, seizures, and coma are accompanied by euphoria with increasing doses. Cocaine stimulates the medullary vasomotor center resulting in hypertension and tachycardia. Small doses may produce transient bradycardia. At high levels, the medullary center may be depressed, leading to respiratory depression.

Peripherally, cocaine blocks the adrenaline and noradrenaline reuptake and induces noradrenaline presynaptic release. This results in a sympathomimetic response mediated by both α- and β-adrenoreceptors resulting in tachycardia, diaphoresis, vasoconstriction, and hypertension. Increased psychomotor activity, vasoconstriction, and direct hypothalamic toxicity, possibly mediated by dopamine receptors, contribute to hyperpyrexia.

Cocaine is an ester-type local anesthetic that blocks fast sodium channels. Hypotension can develop in severe toxicity due to a direct toxic effect on the myocardium. Wide complex tachyarrhythmias with toxicity to cocaine are observed. Sodium channel and potassium channel blockade occur, in addition to sympathomimetic, ischemic, and cardiomyopathic

effects. Arrhythmias are multifactorial; factors include dose, co-exposures, acid-base and electrolyte imbalance, and genetic variability. Transient arrhythmias may account for syncope not attributable to seizures.

Clinical Features

The predominant symptoms are those of excitation in the CNS and sympathomimetic peripheral response. Manifestations of CNS include agitation, impaired mental status, seizures, dyspnea, intermittent neurological focal signs, intracranial hemorrhage, and coma. Cerebral infarction, transient ischemic attacks, subarachnoid hemorrhage, cerebral vasculitis, and migraine-like headache are outlined. Contributing mechanisms include hypertension, vasoconstriction, vasculitis, increased coagulability, altered cerebrovascular autoregulation, and embolization of particulate matter.

Cardiovascular signs include tachycardia, stroke, tachydysrhythmias, supraventricular or ventricular, and syncope. Chest pain may be due to musculoskeletal, pulmonary, or cardiovascular problems. Cocaine-induced myocardial ischemia is multifactorial; increased myocardial oxygen demand, immediate or delayed coronary artery vasospasm, increased platelet aggregation, impaired thrombolysis, and accelerated atherosclerosis all contribute. Aortic dissection associated with cocaine use is reported. A retrospective study of cocaine-intoxicated patients with ischemia-consistent chest pain found that 6% had an acute myocardial infarction.

Smoking cocaine may lead to respiratory complications including thermal airway injury, pneumothorax, pneumomediastinum, noncardiac pulmonary edema, interstitial pneumonitis, and bronchiolitis obliterans. Tachypnea, mydriasis, tremor, diaphoresis, and hyperpyrexia may also be seen. Mesenteric vasoconstriction and vasculitis may lead to bowel ischemia and infarction. Rhabdomyolysis complicated by renal failure and hyperkalemia is reported.

Withdrawal symptoms include depression, tiredness, increased appetite, insomnia, vivid unpleasant dreams, slowed movement, and restlessness.

Differential Diagnosis

The differential diagnosis includes intoxication with other sympathomimetic agents, hallucinogenic agents, anticholinergic delirium, serotonin syndrome, alcohol and benzodiazepine withdrawal, sepsis, thyrotoxicosis, and pheochromocytoma.

Clinical Investigations

The diagnosis is clinical, based on history, sympathomimetic symptoms and signs, and the exclusion of other conditions. Physical examination and investigations are directed at excluding complications and alternative diagnoses. Patients with altered vital signs should have a blood glucose measurement, 12-lead electrocardiogram (ECG), and continuous ECG monitoring.

Treatment

Patients with CNS agitation or cardiovascular sympathomimetic symptoms should get an intravenous benzodiazepine titrated to achieve sedation. Hyperthermia and seizures warrant rapid resuscitation (as in the case of amphetamines) to prevent poor outcomes. Seizures should be managed with benzodiazepines and barbiturates, escalating to general anesthesia if required.

Benzodiazepines, nitrates, and calcium channel blockers reduce hypertension and cocaine-induced vasoconstriction causing chest pain/myocardial ischemia. The use of β-adrenergic receptor blockers in cocaine intoxication is controversial due to the theoretical possibility of unopposed alpha stimulation, which exacerbates hypertension. Combined beta- and alpha-blockade agents (e.g., labetalol) are associated with less complications. Primary angioplasty is the treatment of choice for myocardial infarction due to cocaine-induced ST-elevation. Ventricular arrhythmias should be treated as per Advanced Cardiac Life Support (ACLS) protocol. In addition to defibrillation or cardioversion, intravenous bolus bicarbonate (1–2 mEq/kg) and titrated benzodiazepines are used. One suitable alternative is lignocaine. Ventricular arrhythmias occurring after the acute phase of intoxication are presumed to be secondary to myocardial ischemia and should, therefore, be treated in a standard manner. In patients with nondiagnostic ECG, an investigation should proceed as for nontoxicological chest pain.

Body Packers and Body Stuffers

Body packers are planned; large (usually) amounts of illicit drugs are ingested in their body (usually the GI tract) for the purpose of transport. Body stuffers are unplanned; drugs are ingested without a plan to avoid being caught (usually while being chased by police). Treatment includes cardiac monitoring, whole bowel irrigation with pack count, or immediate transfer to operation theatre if signs of hemodynamic instability, obstruction, or rupture are present. The criteria for discharge include three packet-free stools, reliable packet count consistent with ingestion, and normal contrast study.

Disposition

Disposition depends on the level of toxicity, co-ingested products, complications, and comorbidities. Patients with mild intoxication may be observed in the ED and discharged when the patient is asymptomatic with normal vital signs and mental status. Behavioral therapies such as Cognitive Behavioral Therapy (CBT) contingency management, motivational incentives community based recovery guidance should be introduced.

SUMMARY

Emergency Physicians are at the forefront of recognition of drugs of abuse substances as these are ever changing and involve manipulation of basic chemical structures to avoid legal ramifications. In the era of internet, substances are available from around the world for individuals. Some of these drugs include synthetic cathinone, phenethylamines, piperazines, herbal products, prescription drugs, and many other substances. These substances also known by various common street names. Many drugs of abuse result in psychoactive and sympathomimetic effects with excited delirium. Regardless of the street name or chemical formulations, drug ingested, the mainstay of management includes symptom-based goal directed supportive care with benzodiazepines as useful adjunct.

207 CHAPTER

Alcohol

Ajay Singh Thapa, Devendra Richhariya

INTRODUCTION

Alcohol is one of the most available and consumable fermented drinks worldwide. There are several alcohols (e.g., ethanol, methanol, isopropyl glycol), which consist of at least one organic compound of the hydroxyl functional group (–OH) bound to a saturated carbon atom. The word "alcohol" is derived from the Arabic *kohl* (Arabic: الكحل, Romanized: *al-kuḥl*), a powder used as an eyeliner. The meaning of alcohol was extended to distilled substances in general and then narrowed to ethanol, when "spirits" was a synonym for hard liquor.

Alcohol (ethanol), which is a neuropsychoactive substance, causes numerous systemic effects on the nervous system as well as on other organs and systems. Its effects depend on the percentage of concentration, dose ingested, genetic factors, and the behavior of the consumer. The potential effects of alcohol include impairment in attention, cognition, and dexterity. It also causes aggressive impulses and loss of behavioral control and life-threatening alcohol poisoning. Alcohol intoxication is a major public health issue and plays a large role in alcohol's contribution not only to the global burden of disease through its role in alcohol-related injuries, including intentional injuries, but also to other health conditions that lead, e.g., to cardiovascular deaths.

ALCOHOL INTOXICATION

Globally, an ethanol intoxication is associated with numerous complications, including road-traffic accidents, domestic violence, homicide, and suicide. Preventable death from alcohol poisoning remains a major public health concern. Alcohol is one of the ancient fermented brews that existed at least as early as 10000 BC. In ancient India, alcohol was distilled and used between 3000 BC and 2000 BC as a Sura.

In recent contemporary societies, alcoholic beverages are considered as a routine part of the social lifestyle in most of the populations of the world. Alcohol has considerable toxic effects on the digestive and cardiovascular systems. Alcoholic beverages are classified as carcinogenic by the International Agency for Research on Cancer and increase the risk of several cancer types. Alcohol, as an immunosuppressant, increases the risk of infectious diseases, including tuberculosis and human immunodeficiency virus (HIV).

Epidemiology

Worldwide alcohol consumption contributes to around 3 million deaths each year as well as to the disabilities and poor health of millions of people. Generally, unsafe use of alcohol is responsible for 5.1% of the global burden of disease. Harmful use of alcohol is accountable for 7.1% and 2.2% of the global burden of disease for males and females, respectively. Alcohol is one of the leading risk factors for premature mortality and disability among the working population aged between 15 and 49 years.

Disadvantaged and especially vulnerable populations have higher rates of alcohol-related death and hospitalization. The amount of lifetime alcohol use and a combination of circumstance, frequency of alcohol consumption, and the amount consumed per occasion increase the risk of the various range of health and social harms. The substitutes and illegally fermented alcohols can cause an extra health risk from toxic contaminants. The World Health Organization is currently developing an action plan (2022–2030) to effectively implement the global strategy to reduce the harmful use of alcohol as a public health priority.

Pathophysiology

Ethanol (CH_3CH_2OH) is a water-soluble, low molecular weight, hydrocarbon that rapidly crosses cell membranes. Absorption of ethanol occurs via the gastrointestinal system, primarily in the duodenum and the remainder of the small intestine (~80%) and stomach (~20%). When the stomach is empty, peak blood ethanol levels are reached between 30 and 90 minutes after ingestion.

The primary pathway of ethanol metabolism occurs in the liver via alcohol dehydrogenase (ADH). ADH is also located in the gastric mucosa. The enzyme is found in decreased quantities in women. Less "first-pass metabolism," combined with a smaller volume of distribution, may explain the enhanced vulnerability of women to acute complications of ethanol intoxication. Ethanol is metabolized to acetaldehyde by ADH. Acetaldehyde is metabolized to acetate by acetaldehyde dehydrogenase (ALDH). Acetate is used by the muscle cells to produce acetyl-CoA using the enzyme acetyl-CoA synthetase, and the acetyl-CoA is then used in the "Kreb's cycle." Hypoglycemia occurs due to ethanol's inhibition of

gluconeogenesis, especially in children, and may cause lactic acidosis, ketoacidosis, and acute kidney injury.

In the central nervous system (CNS), alcohol enhances the inhibitory neurotransmitters γ-aminobutyric acid type A (GABA-A) receptor, 5-HT3 receptor, and glycinergic and cholinergic receptors causing sedative effect followed by coma and respiratory failure. It also inhibits excitatory neurotransmitters such as N-methyl-D-aspartate (NMDA), dihydropyridine-sensitive L-type calcium channel, and G-protein activated inwardly rectifying K^+ channels leading to the behavioral and symptomatic effects of alcohol intoxication.

Clinical Presentation

A patient's clinical features depend on the amount of alcohol and time of consumption as well as on the percentage of alcohol in the beverages. The clinical picture of intoxication levels differs from person to person and in the same person from time to time. The condition of liver functions may alter the presentation of disease due to their ability to metabolize to the acetoacetate by ADH enzymes. A picture of an average intoxicated person is given in **Table 1**.

TABLE 1: Blood alcohol concentration and related clinical presentation.

Blood alcohol concentration (BAC)*	***Clinical presentation***
0.00–0.05	Most of these people appear clinically normal. Some of them have a euphoria. Reaction time is slowed down two times
0.05–0.10	Loss of inhibitions, self-criticism, and exaggerated self-confidence. Loss of concentration and normal judgment. Affected coordination. Reaction time is slowed down four times
0.10–0.15	Further loss of self-criticism, emotional instability, memory problems. Early ataxia, apraxia, and agraphia. Reaction time is slowed down further. Orientation concerning time, place, and person may be affected
0.15–0.25	Ataxia, agraphia, apraxia. Coordination severely affected. Loss of orientation. Emotional instability. Balance disturbances. Apathy and emotional eruptions. Numbness and slowed reaction to pain stimuli. Partial amnesia
0.25–0.35	Worsening of the above-mentioned. Total loss of muscle coordination. Apathy and sometimes stupor. Total loss of orientation. Amnesia
0.35–higher	Stupor followed by coma. General anesthesia and paresis. Suppression of the vital centers in the brain with cardiorespiratory collapse and death

*To convert serum ethanol level (mg/dL) to BAC, move the decimal point three places to the left. For example, a 100-mg/dL serum ethanol level is equivalent to a 0.10 (g/dL) BAC or 0.10% (weight/volume). This means that one tenth of 1% of blood in their body is alcohol or a person has 1 part alcohol per 1,000 parts blood.

Diagnosis

There are various nonspecific clinical features, which may cause difficulty to identify the intoxication. However, the Diagnostic and Statistic Manual of Mental Disorders (DSM-5) elaborated the criteria for the diagnosis as follows:

- Recent ingestion of alcohol
- Clinically significant problematic behavioral or psychological changes (e.g., inappropriate sexual or aggressive behavior, mood liability, impaired judgment) that developed during, or shortly after, alcohol ingestion.
- One (or more) of the following signs or symptoms developing during, or shortly after, alcohol use:
  - Slurred speech
  - Incoordination
  - Unsteady guilt
  - Nystagmus
  - Impairment in attention or memory
  - Stupor or coma
- The signs or symptoms are not attributable to another medical condition and are not better explained by another mental disorder, including intoxication with another substance.

The definitive diagnosis is based on the measurement of blood alcohol concentration (BAC). In some countries, the law enforcement officers may use the breathalyzer test for a rapid test as an alternative. Alcohol intoxication is often defined as a BAC of >5.4–17.4 mmol/L (25–80 mg/dL or 0.025–0.080%). This can be measured by blood or breath testing. Alcohol is broken down in the human body at a rate of about 3.3 mmol/L (15 mg/dL) per hour.

Management

Acute intoxication of alcohol is an emergency due to the risk of death from aspiration of vomit, and respiratory depression occurs while the patient is unresponsive. The management of acute toxicity is good supportive care. In the emergency department (ED), gastric lavage is not advocated because it may be harmful and cause aspiration and death. The activated charcoal is not useful because it does not bind and adsorb the alcohol in the gastrointestinal tract. Utmost important in ED is to maintain and secure the airway by basic airway management (chin lift and jaw thrust) or endotracheal intubation followed by mechanical ventilation. Circulation failure and dehydration must be prevented by giving intravenous fluids. Hypoglycemia is a major problem as it inhibits gluconeogenesis and causes complications such as CNS depression, pancreatitis, and local phlebitis. Hypoglycemia should be corrected and euglycemia should be maintained.

Metadoxine, also known as pyridoxine-pyrrolidone carboxylate, administered orally at 500–1,000 mg/day or parentally at 300–600 mg/day enhances elimination of alcohol from blood and improves the clinical conditions. The role of vitamin B1 (thiamine) in chronic alcohol is to prevent Wernicke's encephalopathy (WE) secondary to thiamine deficiency. It is also beneficial in acute intoxication. WE is characterized by abnormal mental status, ataxia, and nystagmus and requires daily treatment with thiamine, 100 mg intravenously every 6 hour, until a normal diet is resumed. Pyridoxine 50 mg/6 hour inhibits the metabolism of glyoxylic acid and favors the formation of less toxic metabolites.

Hemodialysis can be considered in life-threatening situations, e.g., blood alcohol concentration >400 mg/dL, pH <7.1 despite sodium biocarbonate infusion and coma.

Prognosis depends on the initial alcohol blood level and overall general physical conditions. Heavy alcohol consumption may cause memory loss and adverse health conditions. A normal liver detoxifies the alcohol over a period of time and improves the clinical conditions if given good supportive care.

ALCOHOL WITHDRAWAL SYNDROME

Ethanol is a CNS depressant and in low concentration, it produces euphoria and behavioral excitation (increase glutamate binding with the NMDA receptors). But by ingestion of a high concentration of ethanol, acute intoxication occurs due to GABA effects through delta subunit of the receptors. Cerebellum, cortical areas, thalamic relay circuitry, and brainstem are mainly involved in acute intoxication. Tolerance and physical dependence develop with prolonged use of ethanol. GABA receptor downregulation increases glutamate production by NMDA to maintain CNS neurotransmitter hemostasis. Sudden stopping of chronic alcohol consumption results in autonomic overactivity and neuropsychiatric complications, such as delirium and seizures, by unmasking these compensatory changes with a glutamate-mediated CNS excitation.

Clinical Features

Alcohol withdrawal syndrome (AWS) occurs due to sudden stopping or reduction of chronic alcohol consumption which gives rise to a wide variety of clinical presentations ranging from nausea and vomiting, loss of appetite, diaphoresis, insomnia, tachycardia, anxiety, craving, hand tremors, fever, agitation, and hyperexcitation to more concerning features such as hallucination, seizures, and delirium tremens (DTs; **Table 2**). Alcohol withdrawal starts after 6 hours of stopping the alcohol consumption and symptoms may last for 10–15 days.

Chronology of the Symptoms

Symptoms start around 6 hours after cessation or decrease in intake and last up to 4–48 hours (early withdrawal). Hallucinations of visual, tactile or auditory qualities, and illusions while conscious are symptoms of moderate withdrawal. They can last up to 6 days. The appearance of acute symptomatic seizures may emerge 6–48 h after the last drink. 19 DT (onset 48–72 h after cessation of drinking) represent characteristics of severe withdrawal that may last for up to 2 weeks (late withdrawal). The chronological development of the various symptoms is illustrated in **Figure 1**.

Diagnosis of Alcohol Withdrawal Syndrome

The DSM-5 outlines diagnostic criteria for AWS using two main components so that the AWS is diagnosed when the following two conditions are met: (1) A clear evidence of cessation or reduction in heavy and prolonged alcohol use, and (2) The symptoms of withdrawal are not accounted for by a medical or another mental or behavioral disorder.

TABLE 2: Common signs and symptoms of alcohol withdrawal syndrome.

Symptoms	*Signs*
Autonomic symptoms	Tachycardia, tachypnea, dilated pupil, hypertension fever, nausea and vomiting, diarrhea, diaphoresis
Motor symptoms	Hand tremors, tremulous, body ataxia, seizure, gait disturbance, dysarthria, hyperreflexia
Awareness symptoms	Irritability, insomnia, agitation, delirium, disorientation
Psychiatric symptoms	Anxiety, illusion, delusion, hallucination, paranoid ideas, disinhibition, combativeness
Time-dependent evolution of alcohol withdrawal symptoms	• 6–24 h (minor symptoms): Nausea and vomiting, anxiety, tremor • 24–36 h: Alcohol withdrawal hallucinations, mostly tactile • >36 h: Withdrawal, seizures, GTCS single or multiple • >48 h: Delirium tremens—agitation, disorientation, hallucination

(GTCS: generalized tonic-clonic seizure)

Useful Markers in an Emergency Department Setting

According to various studies, a high-risk patient with severe AWS (DT) can be predicted on the basis of medical history or a history of similar events, and if the patient is unconscious, laboratory markers are helpful in suspected cases. The quantitative, measurable detection of drinking is important for the successful treatment of alcohol-use disorder (AUD). Therefore, the importance of direct and indirect alcohol markers to evaluate consumption in the acute clinical setting is increasingly recognized. A summary of relevant markers in the emergency setting is given in **Table 3**. Severe alcohol withdrawal symptoms should be differentiated from hyponatremia, hepatic encephalopathy, infections (pneumonia, meningitis) thyrotoxicosis, head injury, psychosis, and drugs intoxication (tricyclic antidepressant, lithium, atropine).

Neuroimaging is recommended to rule out any other neurologic condition, especially those associated with first-onset seizures or generalized tonic-clonic seizures.

Tools for Predicting and Assessing Severity of Alcohol Withdrawal Symptoms

The PAWSS (Prediction of Alcohol Withdrawal Severity Scale) is the first validated tool to identify patients at risk for severe alcohol withdrawal symptoms such as seizure and DT. This will help in starting prophylaxis for AWS before severe symptoms occur. There are several validated scales for the assessment of symptoms and pharmacotherapy intervention. Practicability and objectiveness depend on the qualitative and quantitative awareness of the patients. If a patient is uncooperative or

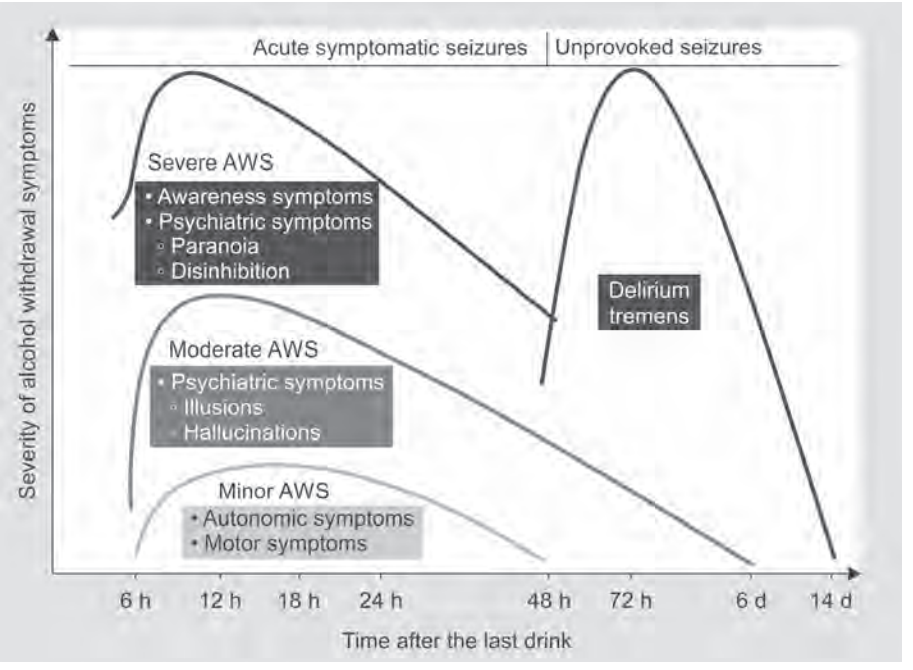

FIG. 1: Chronological development of the alcohol withdrawal symptoms (AWS).

TABLE 3: Relevant markers of alcohol-use disorder in an emergency department setting.

Markers	***Significance***
Ethanol	Estimated in breath, blood urine up to 6–24 h, 90–95% specificity
Hypokalemia	Estimated in blood up to days to weeks, 40% specificity. Serum levels <2.5 mEq/L indicates alcohol-use disorders
Thrombocytopenia	Estimated in blood up to days to 10–12 days, 70–75% specificity. Rebound thrombocytosis after cessation of alcohol abuse
Mean corpuscular volume	Estimated in blood up to days to months, specificity 80%, dose-dependent increase
γ-glutamyl transferase	Estimated in blood up to days to weeks, specificity 80%, marker of liver injury due to alcohol-use disorder
Ratio AST/ALT >2	Estimated in blood AST 18 h ALT 36 h, specificity 80%, marker of liver injury due to alcohol-use disorder

(ALT: alanine transaminase; AST: aspartate transaminase)

sedated, these tools are replaced by those generally applicable to patients admitted to the intensive care unit such as the Richmond Agitation-Sedation Scale. Alcohol Withdrawal Scale is less dependent on patient participation and his/her response that cover the whole spectrum of withdrawal syndromes including delirium. The most widely used tool for clinical estimation of the severity of AWS based on observations and patient participation is Clinical Institute Withdrawal Assessment for Alcohol scale (CIWA-Ar). Five clinical parameters (heart rate, respiratory rate, temperature, sweating, tremor) and five psychological parameters (agitation, anxiety, tactile disturbances, disorientation, and hallucinations) are used for assessment.

Treatment

Treatment of AWS is mainly based on control of agitation, autonomic hyperactive symptoms, and DT. Later, detoxification therapy and motivation for prolonged abstinence are recommended. Intravenous benzodiazepine is used as the initial therapy. No specific benzodiazepine is superior to one another (**Table 4**). Adjunctive therapeutic agents can also be added. Chronic alcohol use is associated with abnormal magnesium metabolism. Magnesium is an important part of many coenzymes and acts as inhibitors of neurotransmitter. It competes with glutamate in its receptor-binding sites and decreases NMDA-induced hyperexcitability. Electrocardiogram (ECG) for QT interval and lab value should be estimated to balance the deficiency. Early thiamine supplementation is helpful in faster recovery from WE regardless of the initial clinical presentation. WE is a classic triad of confusion, ataxia, and ophthalmoplegia. According to the European Federation of Neurological Society (EFNS) guideline for diagnosis of WE, two of the following four signs are required: (1) Dietary deficiencies, (2) eye signs, (3) cerebellar dysfunction, and (4) either an altered mental state or mild memory impairment. Severe alcohol withdrawal symptoms, especially with delirium, are difficult to differentiate from WE. Prevention of WE with parenteral thiamine is easy and uncomplicated and should be administered to all patients at risk, including those experiencing alcohol withdrawal symptoms and prior to any parenteral carbohydrate-containing fluids.

METHANOL POISONING

Methanol is methyl alcohol, also known as wood alcohol or wood naphtha. It is a colorless, water-soluble liquid with a typical aromatic odor and slightly bitter taste. Industrial methylated spirit consists of 95% ethyl alcohol and 5% methyl alcohol. Mineralized methylated spirit contains 90% ethyl alcohol and 10% methyl alcohol. Surgical spirit contains 95% ethyl alcohol and 5% methyl alcohol in which oil of wintergreen

TABLE 4: Alcohol withdrawal syndrome.

Uncomplicated alcohol withdrawal symptoms	*Complicated alcohol withdrawal symptoms*	
	Alcohol withdrawal seizure	*Alcohol withdrawal delirium tremens*
• IV diazepam 10–20 mg or • IV lorazepam 2–4 mg and • IV ondansetron 4 mg (if vomiting)	IV lorazepam 2 mg	• IV lorazepam 2–4 mg can be repeated with double dose till mild sedation or • IV diazepam 10–20 mg over 2 min can be repeated with double dose till mild sedation
• Lorazepam 2 mg orally • Diazepam 10–20 mg orally • Oxazepam 15–30 mg orally		• If symptoms are refractory to benzodiazepine, • IV phenobarbital 65 mg every 30 min or propofol 5 µg/kg/min (requires intubation as respiratory depression is more than benzodiazepine)
Alcohol-induced psychotic disorder is treated with antipsychotic drugs and abstinence from alcohol		

is added for sweetish aromatic flavor for easy detection and pleasant use. It is used in many home chemicals, duplicating fluids, varnishes, stains, paint thinners, and dyes. Methylated spirit is very cheap and frequently available; hence, it is easily adulterated and used as country liquor among poor people who cannot afford ethyl alcohol for their drink.

Absorption, Distribution, and Excretion

The specific gravity of methanol is 0.81 (ethanol is 0.79), i.e., 1 L contains 810 g of methanol. It is rapidly absorbed from the intestine and to a small extent from the stomach. Its rate of absorption is more than glucose. The absorption depends upon concentration (the higher the concentration, the rapid the absorption) and the condition of the stomach (in empty stomach—rapid absorption) and is completed within 3 hours. If the concentration is below 20%, it increases gastric secretion. After absorption from blood, it mostly goes to the intracellular and extracellular fluid of the tissue and less to body fat. When the absorption is completed, urine and cerebrospinal fluid (CSF) contain 20% more alcohol than blood. About 90% of the alcohol is oxidized in the liver. Rest is excreted through urine and exhaled air. Its oxidation and excretion are much slower than ethyl alcohol. In the presence of ethyl alcohol its absorption, metabolism, and excretion are further delayed.

Mechanism of Toxicity (Metabolism)

Methanol itself is a less toxic agent. It becomes highly toxic when it is mixed with ethyl alcohol as it is adulterated. The rate of oxidation is very slow, only about 15% of that of ethyl alcohol. When taken with ethyl alcohol, it is metabolized only after complete metabolization of ethyl alcohol. In course of oxidation, formaldehyde and finally formic acid are formed which are highly toxic. Ethyl alcohol is preferentially metabolized by ADH resulting in reduced methanol toxicity.

Action, Clinical Features, and Fatality

- *Central nervous system toxicity*: It depresses CNS causing headache, dizziness, vertigo, dyspnea, cyanosis, cardiac depression, and muscular weakness. It is a less respiratory depressant than ethyl alcohol, but its delayed effects are very dangerous which include optic nerve atrophy resulting in complete blindness. The delayed toxicity may take 6–72 hours (usually 12–24 hours) to develop.
- *Ocular toxicity*: It is a delayed feature, which includes blurring of vision, which gradually leads to total or partial blindness. On examination pupillary dilatation, retinal edema, and hyperemia of the optic disk may be found. About 20% of the victims become totally blind; others have a different form of visual disabilities.
- *Renal toxicity*: There may be scanty micturition, which is acidic and contains acetone and format; sometimes there may be total anuria.
- *Gastrointestinal tract toxicity*: It includes nausea and abdominal pain. About 40% of the methanol users have high amylase level.
- *Respiratory toxicity*: There may be dyspnea, respiratory distress, and death usually due to respiratory failure.

Laboratory Diagnosis

Methanol poisoning causes an elevated osmolar gap, which may be detected by the difference between the measured and the calculated osmolarity. Osmolarity is calculated by the formula:

$$\text{Osmolarity} = (2 \times \text{Na}) + (\text{BUN}/2.8) + (\text{Glucose}/18).$$

A serum level of 200 mg/dL of methanol adds approximately 62 mOsm/L to the osmolar gap.

Methanol also produces high anion gap acidosis, which is due to excessive production of formic acid and lactic acid.

Management

The intoxicated person must be hospitalized and kept under close observation, even after initial recovery. He must be treated by an ophthalmologist for his visual problems. Initial management is given in the following text.

There is no evidence of effectivity of stomach wash although it is advocated. Oxygen inhalation and artificial respiration are recommended in moderate cases. In a severe case, the patient should be intubated and mechanical respiration should be given. Circulation should be maintained by giving fluids and sympathomimetics. Fluid–electrolyte balance should be maintained and dehydration should be combatted. Acidosis should be controlled by infusing sodium bicarbonate. Renal failure should be monitored carefully. Sedation can be given cautiously to prevent delirium and restlessness. Eyes should be protected from light and should be under regular observation.

Ethyl alcohol therapy is given to delay the absorption and metabolism and thus to prevent the damaging effect of methanol.

In methanol poisoning, start folinic acid 1 mg/kg (maximum dose is 50 mg): Repeat every 4 hourly to protect against ocular toxicity. Since alcohol (ethanol and methanol) is metabolized by ADH so the primary treatment is to block this

enzyme. *Fomepizole,* also known as 4-methylpyrazole, can be used alone or with hemodialysis to treat methanol and ethylene glycol poisoning. A dose of 15 mg/kg loading is administered followed by 10 mg/kg every 12 hour (total of four doses) till serum ethanol is <20 mg/dL. In case of dialysis, 4 hourly doses are required as it is dialyzable. Studies highlighted greater safety of fomepizole than ethanol (alternative) in the treatment of methanol poisoning.

The (alternate) antidote for methanol poisoning is ethanol. Absolute alcohol is suitable for IV use. Ethanol is given orally or IV to maintain a blood ethanol level of 100–150 mg/dL. This will block methanol metabolism. In mild poisoning, oral ethanol is adequate. Give 10% ethanol 7.5 mL/kg IV, over 30–60 minutes, as a loading dose. The recommended maintenance dose for nondrinkers is 10% ethanol 1 mL/kg/h IV. For chronic ethanol drinkers, the maintenance dose is 10% ethanol 1.96 mL/kg/h IV. If the patient is undergoing hemodialysis, the maintenance dose is 3 mL/kg/h. A solution of about 10% ethanol can be made by mixing 60 mL of absolute alcohol suitable for IV use in 500 mL of 5% dextrose.

Ethanol can be administered orally if the IV preparation is not available. Concentrations <20% are preferred to avoid gastric irritation. A loading dose of 95% ethanol, 0.8 mL/kg followed by 0.1 mL/kg/h can be given. If the patient is undergoing hemodialysis, increase the dose up to 0.2 mL/kg/h and administer via a nasogastric tube. For chronic ethanol drinkers, the maintenance dose is 0.2 mL/kg/h. The alcohol should be diluted in water or fruit juice.

If no alcohol is available in the hospital, give arrack (gin or whisky) 1.8 mL/kg as a loading dose and 0.2 mL/kg/h as maintenance dose orally, after diluting with water or fruit juice. If the patient is undergoing hemodialysis, the maintenance dose is 0.7 mL/kg/h. Dose should be loading with 50 g of 50% ethyl alcohol (e.g., 125 mL of gin, whisky, or vodka) orally followed by a further oral dose for 3–4 days or an IV infusion of 10–12 g ethanol/hour, to achieve a blood concentration of about 500–1,000 mg/L.

Ethanol should be given until methanol is undetected in the blood. A serum ethanol level of 100 mg/dL is essential to achieve the best counter-effect of methanol. The above regimens should be maintained for 2–3 days unless contraindicated for any reason or until plasma methanol concentration is <20 mg/dL. The blood ethanol level should be monitored hourly initially, and at longer intervals thereafter, depending on the facilities available. As prolonged ethanol administration can cause hypoglycemia, especially in children, determine blood glucose levels and give glucose orally or 5% or 50% dextrose IV. If convulsions are present, give diazepam 5–10 mg IV (pediatric dose: 0.2 mg/kg). Repeat if necessary.

Hemodialysis is effective in removing the absorbed poison and its metabolites. Indication for dialysis: (1) If ingest >30 g methanol, (2) develop metabolic acidosis (pH 7.1 rise in creatinine) or mental, visual, or fundoscopic abnormalities attributable to methanol, and (3) has a blood methanol concentration >500 mg/L. Hemodialysis is more effective than peritoneal dialysis. If dialysis is used, increased quantities of ethanol (17–22 g/h) must be administered.

Medicolegal Importance

Most of the poisonings are accidental, due to adulteration with methylated spirit and other narcotics, but postmortem reports always go in favor of suicide as it is self-taken. Homicide is very much uncommon.

SUMMARY

Alcohol is one of the most available and consumable fermented drinks worldwide. Alcohol (ethanol), which is a neuropsychoactive substance, causes numerous systemic effects on the nervous system as well as on other organs and systems. Globally, an ethanol intoxication is associated with numerous complications, including road traffic accidents, domestic violence, homicide, and suicide. AWS occurs due to sudden stopping or reducing of chronic alcohol consumption which gives rise to a wide variety of clinical presentations. Treatment of AWS is mainly based on control of agitation, autonomic hyperactive symptoms, and DT. Methanol becomes highly toxic when it is mixed with ethyl alcohol as it is adulterated. Vulnerable populations have higher rates of alcohol-related death and hospitalization. Knowledge about alcohol-related problems and their management is extremely important for an emergency physician.

208
CHAPTER

Cardiovascular Drug Overdose

Rahul Solanki

INTRODUCTION

Cardiovascular drugs such as β-adrenergic antagonists (BAAs), calcium channel antagonists (CCAs), angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, etc. are widely used for cardiovascular diseases.These are among the most significant determinants of morbidity and mortality in the entire world. Because of the widespread use of these drugs, their overdose is also common. Mostly, the overdose is unintentional but the intentional use is not uncommon. The proportion of intentional overdose is also significant typically in the younger population with less burden of cardiovascular disease. Sudden cardiac death in a young healthy person is most likely to be drug-related. Poisoning is the leading cause of cardiac arrest in patients younger than 40 years of age but infrequent in elderly patients. Drug-induced adverse cardiovascular events include:

- Myocardial injury—most common. Presence of electrocardiogram (ECG) changes and elevated biomarkers
- Shock—second most common. Hypotension or hypoperfusion requiring vasopressors
- Ventricular dysrhythmias—third most common. Ventricular tachycardia/fibrillation, torsade de pointes
- Cardiac arrest—loss of pulse requiring cardiopulmonary resuscitation (CPR)

Adverse cardiovascular events from hospitalized drug overdose patients are as high as 17%. This high morbidity implies that physicians should always exercise caution while prescribing these drugs. Determinants of dose such as age, renal, and liver function should also be kept in mind. To manage these, a patients proper assessment of hemodynamic status remains important so that pathophysiological derangement can be dealt with effective therapy.

Besides many other drugs, BAA and CCA remain invaluable for the treatment of many cardiovascular and other medical conditions. Unfortunately these drugs are also responsible for cardiovascular collapse after an accidental or intentional overdose. Data suggests that BAA and CCA come only after cocaine as the most common cause of death due to overdose.

β-ADRENERGIC ANTAGONISTS AND CALCIUM CHANNEL ANTAGONISTS

The BAA and CCA are sources of significant morbidity and mortality as both are used widely. Both have a similar presentation in overdose. So the line of treatment is also similar. Both are often refractory to standard supportive care. As both inhibit calcium entry into the cells, both have common clinical features of hypotension and bradycardia.

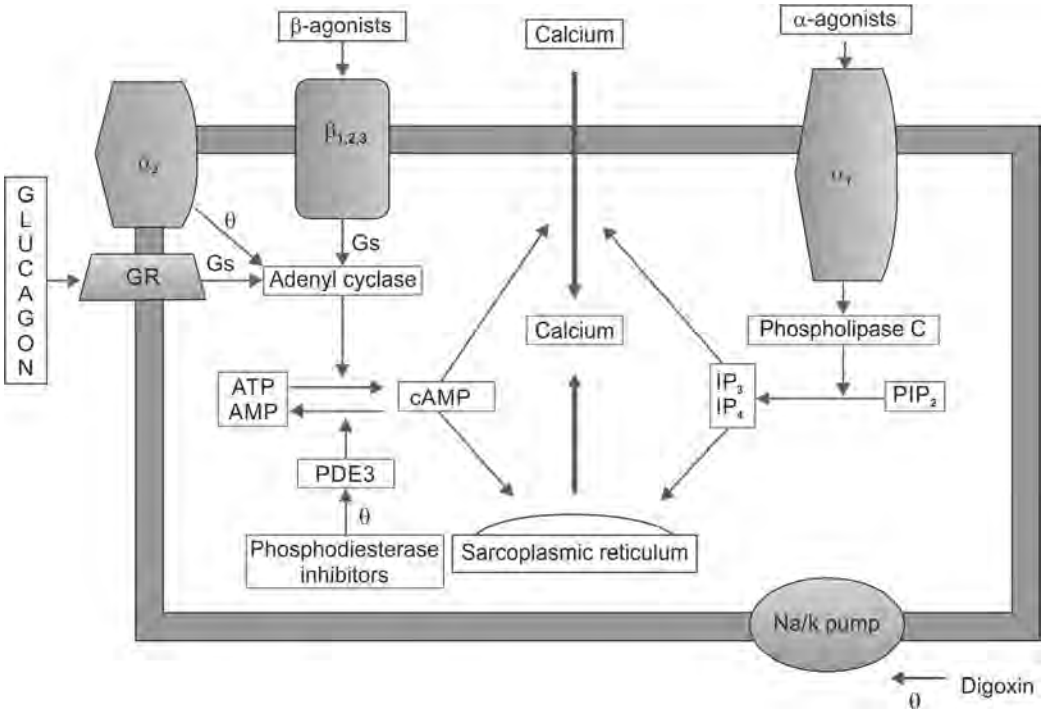
Beta-adrenergic Antagonists

There are three types of β-adrenergic receptors:

1. β_1 receptor primarily regulates myocardial tissue and affects the rate of contraction via impulse conduction.
2. β_2 receptor regulates the smooth muscle and affects bronchiolar and vascular relaxation.
3. β_3 activity increases cardiac inotropy and affects lipolysis.

Calcium Channel Antagonists

Calcium channel antagonists prevent the opening of voltage-gated calcium channels found in the myocardial cells, smooth muscle cells, and β cells of pancreas and reduce calcium entry into the cells during phase 2 of action potential (**Fig. 1**). Inotropy is reduced within the cardiomyocytes as there is lack of intracellular calcium. Vasodilation of vascular smooth muscle also occurs because of calcium channel blockade. Dihydropyridines, such as amlodipine and nifedipine, act predominantly on peripheral vasculature. Nondihydropyridines, such as verapamil and diltiazem, not only are more cardioselective but also have peripheral vascular activity. This leads to a decrease in sinoatrial (SA) and atrioventricular (AV) nodal conduction, myocardial contractility, and peripheral vascular resistance (PVR). Impaired impulse generation can cause sinus bradycardia, complete AV dissociation, and sinus node arrest. Decreased PVR reduces afterload and systemic blood pressure. Because dihydropyridine CCA preferentially acts in the peripheral



(cAMP: cyclic adenosine monophosphate; GR: glucagon receptor; Gs: g protein complex; IP3: inositol triphosphate; PDE3: phosphodiesterase3; PIP: phosphor inositol diphosphate)

FIG. 1: Schematic representation of the action of inotropic drugs on intracellular calcium in myocytes.

vascular system, initial vasodilation with reflex tachycardia may occur. In large overdoses, receptor selectivity is lost and the toxicity of each class is difficult to be differentiated. The voltage-gated calcium channel inhibition of pancreatic β cells results in decreased insulin release.

Clinical Features

Cardiovascular

Cardiovascular adverse effect characterized by hypotension and bradycardia (sinus pause/arrest, junctional escape rhythm, idioventricular rhythm, and AV block) is common to both BAA and CCA. BAA toxicity is typically associated with widened QRS due to sodium channel blockade. It may also have compensatory peripheral vasoconstriction as opposed to vasodilation. Noncardiogenic pulmonary edema is commonly associated with CCB overdose.

Central Nervous System

Lipophilic BAAs (propranolol) are likely to cause sympathetic nervous system (SNS) depression whereas hydrophilic BAAs (atenolol) generally do not produce the same degree of sedation. Although BAA themselves may cause central nervous system (CNS) depression, an inadequately perfused brain also manifests clinically with an altered mental status. Other CNS manifestations include confusion, agitation, and seizures.

Endocrine

Calcium channel antagonist toxicity is likely to result in hyperglycemia. In fact, the degree of hyperglycemia correlates with the degree of cardiotoxicity. But in BAA toxicity, hypoglycemia may occur (especially in children). BAA can also lead to hyperkalemia. It may be difficult to determine the causative agent because of the similar clinical manifestations of BAA and CCA due to their common cardiac effects. Peripheral vasoconstriction and cool extremities, hypoglycemia or euglycemia, sodium channel blockade as well as CNS depression would favor the diagnosis of BAA toxicity whereas peripheral vasodilation, hyperglycemia, noncardiogenic pulmonary edema, and a normal sensorium would suggest CCA toxicity.

In patients who are severely poisoned and not resuscitated properly, tissue hypoperfusion results in lactate-associated acidosis and resultant academia. Similarly, CNS effects including drowsiness, confusion, agitation, and seizures may be observed secondary to hypoperfusion. Acute lung injury, acute kidney injury, and gastrointestinal (GI) ischemia may develop secondary to hypoperfusion and are indicators of poor prognosis.

Management

Gastrointestinal Decontamination

Airway, ventilation, and cardiovascular have precedence over GI decontamination as there is not sufficient evidence that it improves outcome. But in a patient with normal vital signs and who is alert, awake, and oriented, it should be done with activated charcoal. Whole bowel irrigation is done in a patient having an overdose of sustained-release preparation. Polyethylene glycol-based preparation at the rate of 2 L/h (500 mL/h in children) should be used until the rectal effluent is clear. Whole bowel irrigation should be avoided with the onset of symptoms of hypotension and bradycardia as they coincide with depressed GI function and ileus.

Resuscitation and Initial Treatment

All poisoned patients need continuous cardiopulmonary monitoring and immediate and reliable intravenous access. A central venous catheter is required in hypotensive patients as they may need vasopressors. Initial fluid resuscitation with 1–2 L of crystalloid bolus may be required. Be careful to avoid volume overload. IV atropine should be given if there is symptomatic bradycardia or conduction disturbance (dose of 0.5 mg every 3–5 min, total dose 3 mg). If there is shock, its underlying mechanism should be ascertained by echocardiography. This will be helpful in selecting the most appropriate vasoactive agent. Invasive methods, such as pulmonary artery catheter or pulse contour cardiac output, may be used to assess the cardiac output and hemodynamic parameters in patients having shock.

Specific Treatment

Various specific options are available and can be used stepwise and most steps can be selected depending on the response, but sometimes the patient is so unstable due to the severity of the poisoning that several steps will be used simultaneously. Available options are glucagon, calcium chloride/calcium gluconate, high-dose insulin euglycemic therapy (HIET), lipid emulsion, vasopressors, pacemakers, and extracorporeal therapy.

Glucagon

Clinical experience in humans and minimal adverse effect profile support the use of glucagon early in the course of both BAA and CCA toxicity. The first-line therapy in BAA poisoning in patients having symptomatic bradycardia and hypotension is high-dose glucagon (0.1 mg/kg) as it can bypass the β-adrenergic receptor and activate adenylate cyclase (*see* **Fig. 1**). Hemodynamic improvement should occur within 5 minutes of the initial bolus of glucagon. This is immediately followed by a continuous infusion of glucagon at a rate of 2–10 mg/h (maximum dose 10 mg/h) as it has a short duration of cardiac effects. There is no established maximum dose for the continuous infusion; one patient required 411 mg which was given over 41 hours following propranolol overdose. Adverse effects of glucagon include nausea and vomiting and are dose-related. Emesis may be problematic in patients having depressed mentation and difficult airway status. As glycogenolysis is stimulated by glucagon, hyperglycemia may occur which typically does not require any intervention. Vomiting and hyperglycemia occur commonly in diabetics or during continuous infusion. An acute decrease in response to glucagon (tachyphylaxis) may occur after repeated administration. Glucagon is expensive and might not be available in sufficient quantity, so other options such as HIET, and vasopressors can be used.

Calcium Chloride/Calcium Gluconate

Calcium chloride, calcium gluconate, or both can be used. They are expected to increase inotropy and improve blood pressure but have little effect on the heart rate and conduction block. Intravenous calcium is used as a first-line agent in CCA toxicity and to treat BBA toxicity as well depending on improvement in blood pressure and cardiac output.

There are no clear guidelines regarding the form or dose of calcium to use as it is available in two forms.

Calcium chloride contains more calcium in terms of milliequivalents than calcium gluconate. A 10-mL vial of 10% calcium chloride solution contains 13.5 mEq of calcium whereas a similar volume and concentration of calcium gluconate provide 4.5 mEq. When given as equivalent doses, the chloride and gluconate form provide a similar increase in ionized calcium.

Calcium Chloride

About 10 mL of 10% solution (1 g) calcium chloride should be given by central venous access over 5–10 minutes because tissue injury which may occur due to extravasation of calcium preparation is a concern. It can be repeated every 10–20 minutes to a total of 3 g or after the bolus dose, continuous infusion is initiated at a rate of 0.2–0.4 mL/kg/h because bolus administration increases ionized calcium only for a brief period (5–10 min).

Calcium gluconate can be given by a peripheral vein. Starting dose of 30 mL of 10% solution over 5–10 minutes is followed by an infusion of 0.6–1.2 mL/kg/h.

Calcium infusion is titrated to affect either improved blood pressure or contractility. Initially, a serial ionized calcium level is required every 30 minutes and then every 2 hours with a target of maintaining ionized calcium at nearly twice the normal. The required large doses of calcium are usually tolerable without any problem. Rarely calcium administration has potential adverse effects such as hypotension, conduction blockade, bradycardia, and asystole, if given too rapidly. Calcium should not be given inadvertently in a digitalis intoxicated patient who has resultant excessive myocyte calcium overload and asystole. The safest form of available preparation is calcium gluconate.

High-dose Insulin Euglycemic Therapy

Supportive care and traditional treatment are not always sufficient in severe poisoning. HIET for CCA and BAA has been found to have more effect on hemodynamics than traditional measures such as vasopressors. It has emerged as the treatment of choice for severe CCA and BAA toxicity.

High-dose insulin euglycemic therapy exerts its therapeutic effect through two pathways: (1) Increased inotropy, and (2) Vascular dilation. Insulin improves inotropic action through the PI3K pathway and through augmented glucose uptake into myocardial cells, improving energy supply and use. It increases endothelial nitric oxide synthase activity, thereby causing vasodilation of peripheral arterioles in coronary, systemic, and pulmonary vasculature, thus improving perfusion and increasing cardiac output independent of increased inotropy. HIET should be started early when severe poisoning is suspected, even before the hemodynamic instability is profound as the onset of effect usually takes 15–60 minutes and failure of this effect has been seen when it is instituted late. Other causes of treatment failure are insufficient dosing and concomitant use of vasopressor.

The dosage of infusion is not clearly established, mostly a bolus dose of 1 unit/kg of regular human insulin along with 0.5 g/kg of dextrose. This is followed by an infusion of insulin at a rate of 0.5 units/kg/h which can be titrated upward to 2 units/kg/h or high if no improvement is seen after 15–30 minutes. As an improvement in hemodynamic is seen, the dose needs to be uptitrated to a systolic BP of ≥100 mm Hg. If no response is seen in 30–60 minutes, the dose needs to be increased. The glucose requirement does not necessarily increase with an increased

dose of insulin. The concentration of insulin preparation should be 10 units/mL. Similarly, D25W or D50W administration by a central venous catheter may be used to avoid large fluid volume with more dilute solutions. If blood glucose is >300–400 mg/dL, the dextrose bolus is withheld. Glucose should be monitored every 30 minutes for the first 4 hours and titrated to maintain euglycemia (euglycemia is defined as blood glucose between 100 and 250 mg/dL) and then hourly thereafter.

Serum potassium is monitored every hour for the first 4–6 hours with a target potassium level >3 mEq/L. Magnesium and phosphorus levels also need to be monitored. Potassium concentration should also be monitored closely because insulin shifts potassium intracellularly. Replace potassium when it falls below 2.5 mEq/L.

Adverse effects with HIET are predictable and infrequent. They are hypoglycemia, hypokalemia, hypophosphatemia, and hypomagnesemia. To summarize, HIET is a safe and effective therapy for significant CCA and BAA toxicity. Hypodynamic myocardium is the best indication for its use. Early detection of depressed contractility and early initiation of HIET will increase the chance of survival.

Vasopressor

The selection of vasopressor is guided by the type of shock. The goal of therapy should be to improve tissue perfusion and not just to achieve a target blood pressure. There is no single agent that is superior for cardiovascular drug toxicity. In BBA and CCA toxicity, large doses of multiple agents may be required and response might be unpredictable. Norepinephrine appears to be the choice of drug initially due to its strong α_1 agonist [increased systemic vascular resistance (SVR)] and moderate β_1 agonist (increased contractility) activity. Despite having both positive chronotropic and inotropic effects, epinephrine worsens tissue ischemia by hyperglycemia, lactic acidosis, and insulin resistance without improving tissue perfusion in large doses. As there is a lack of efficacy and worsening survival, use of vasopressin has been discouraged. It may be used as an adjunct in severe vasodilatory shock which is not responding to other catecholamines. The dose of vasopressin should never exceed 0.04 IU/min as it can cause reduced cardiac output and limb ischemia. Adverse effects of catecholamine administration include tissue injury, hypotension, and detrimental metabolic consequences. Central intravenous administration is preferable as a potent α-agonist may extravasate from the peripheral intravenous site. Isoproterenol and dobutamine having β-agonist activity and a little α-agonist activity may decrease peripheral resistance and worsen hypotension. an adrenergic agonist may be detrimental during shock as it enhances free fatty acid use by the heart. Because of this detrimental metabolic effect on the heart from catecholamine and marginal efficacy, other cardiotonic agents are a better initial choice when a depressed myocardial function needs to be improved.

Sodium Bicarbonate Therapy

Both BAA and CCA drugs antagonize myocardial sodium channel. Thus, toxicity from these drugs may include widened QRS along with bradycardia. Sodium bicarbonate is used to treat academia and sodium channel blockade. Hemodynamic improvement is also seen after sodium bicarbonate treatment.

Dose: 1–2 mEq/kg (2–4) vials bolus followed by a continuous infusion of 150 mEq/L sodium bicarbonate plus 40 mEq potassium chloride (KCL) at 200 mL/h.

Other Therapies

Phosphodiesterase Inhibition (Amrinone Milrinone Enoximone)

They improve inotropy independent of β-adrenergic receptor by increasing intracellular cyclic adenosine monophosphate (cAMP). But their action on vascular smooth muscle also causes vasodilation and hypotension. They can be considered third-line agents as there is limited evidence of poisoning.

Intravenous Lipid Emulsion

It is recommended as rescue therapy for BAA and CAA toxicity. Its mechanism of action appears to be intravascular sequestration of the toxic drug to an intravascular lipid phase, thereby decreasing the free blood concentration of the drug. It might provide energy to the cardiac myocyte. By increasing the intracellular calcium level, it may also improve the contractility.

Dose: 1.5 mL/kg of 20% lipid emulsion followed by 0.25 mL/kg/min for 30–60 minutes. Maximum dose is 12.5 mL/kg in 24 hours. Adverse effects include pancreatitis, lung injury, and lipemic serum interfering with biochemical tests and there is a possibility of paradoxically increasing absorption of the toxic drug from the GI tract.

Hemodialysis

Hemodialysis can be used in some BAA such as atenolol, nadolol, and sotalol as the binding is <25%, volume of distribution is 2 L/kg, and renal elimination is present. Most other BAA and all three classes of CAA are lipophilic, highly protein-bound, and primarily undergo hepatic metabolism. So extracorporeal drug removal has limited usefulness following overdose of BAA and CCA.

Pacemaker

Pacing may be considered in a case of unstable bradycardia or high-grade conduction disturbances or if shock persists after the administration of the first-line therapy such as calcium, HIET, and vasopressor. However, pacing often fails to achieve electrical capture and if capture occurs, blood pressure is not always restored. The disconnect between electrical capture and lack of improved contractility or increased blood pressure lies in the lack of intracellular calcium necessary for contraction. This is equally true for CCA whereby there is an increased limit required for calcium to enter the myocardium during diastole.

Extracorporeal Life Support

Severe BAA and CCA overdose is responsible for about two third of all deaths due to overdose with cardiotoxic drugs. A subset of patients with shock refractory to traditional approach might benefit from extracorporeal measures. Extracorporeal therapies allow time for drugs to be redistributed or metabolized till the heart function recovers but ineffective in refractory vasodilatory shock. Some reports of successful management of severely poisoned cases with continuous venovenous hemofiltration with charcoal hemoperfusion have been reported. There is

also usefulness of veno-arterial extracorporeal membrane oxygenation (ECMO) in the management of severely poisoned patients having cardiogenic shock or mixed shock with a significant cardiogenic component. Complications include local bleeding and limb ischemia. Timely indication of ECMO has shown to provide a survival benefit, especially in patients refractory to medical therapy.

The overall objective of the therapy is to improve organ perfusion. Since the pathophysiology of the shock could be multifactorial, a multimodal approach for management is needed, based on a careful assessment of the hemodynamic status. Therapy must be individual and multiple simultaneous interventions might be required for the best possible outcome.

CARDIOACTIVE STEROID TOXICITY

Digoxin is a cardioactive steroid (CAS) mostly used in the treatment of congestive heart failure and/or rate control of ventricular response due to atrial fibrillation or flutter. Despite the declined use of CAS, their acute and chronic toxicity is still troublesome even today because of their narrow therapeutic index. Acute overdoses in children are often unintentional and are due to an error in dosing or mistaken ingestion of an adult's medication. The geriatric population is at a particular risk for toxicity because of changes in the absorption, protein binding, elimination, or interaction with other medications. Severe toxicity due to CAS has been reported from consumption of products used for increased sexual performance, male enhancement, herbal colon cleansing, and rodenticides (**Flowchart 1**).

Pathophysiology

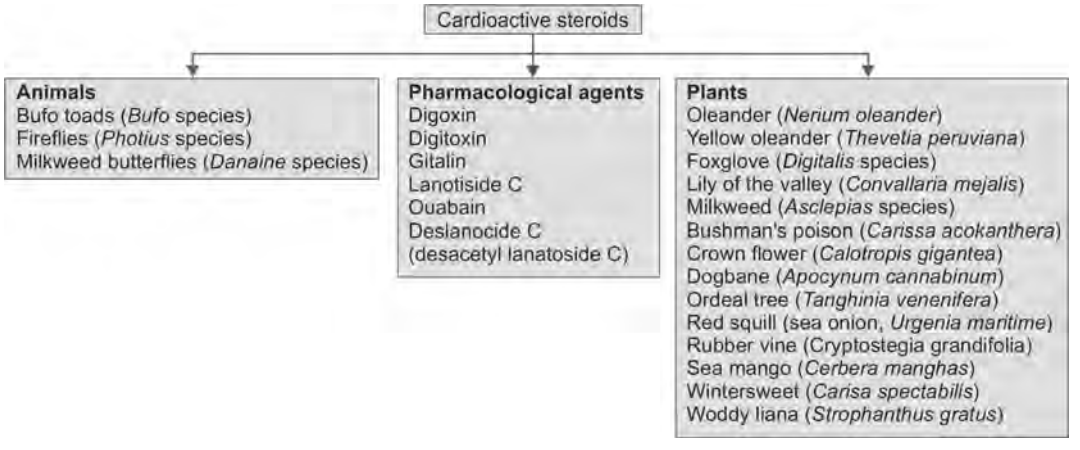
Cardioactive steroids are positive inotropes; as a result, they inhibit active transport of sodium and potassium across cell membrane during repolarization by binding to and inhibiting the sodium–potassium ATPase ($3Na^+$ $2K^+$ ATPase). The end result is an increase in the force of contraction of cardiac muscle due to increased intracellular calcium which induces myocyte sarcoplasmic reticulum to release further calcium. The repolarization interval of cardiac muscle is increased and also shortened by CAS. The conduction through SA and AV nodes is decreased by the concomitant rise in vagally mediated parasympathetic tone. The ECG will show these changes in the form of a prolonged PR interval and a decreased ventricular response rate to atrial stimuli. Ventricular repolarization is also affected via increased intracellular calcium resulting in QT interval shortening and ST-T wave forces opposite to the direction of QRS forces (digitalis effect—scooped ST segment). Hypokalemia increases the chances of arrhythmias by enhancing the automaticity of the myocardium and impairing the activity of $3Na^+$-$2K^+$ ATPase.

Clinical Features

Presentation of CAS toxicity depends on different factors such as age, comorbid condition, renal function, acute or chronic ingestion, identity, and magnitude of the particular drug ingested. All these factors play an important role in determining clinical manifestations. Acute CAS toxicity may occur from accidental, suicidal, homicidal, or recreational exposure to CAS. It should always be kept in mind that the presentation of the patient will depend on the time of ingestion and quantity of the drug. Because of its insidious onset and nonspecific symptoms, it is often difficult to diagnose chronic toxicity. CAS can result in almost any arrhythmia except rapidly conducted supraventricular tachyarrhythmias (due to combined AV node blockade as vagal tone is increased and there is increased ventricular contractility). An ectopic ventricular rhythm is the most common sign of cardiac toxicity. Bidirectional ventricular tachycardia can be said to be nearly pathognomonic of CAS toxicity. When there is evidence of impaired SA/AV nodal conduction combined with increased automaticity, CAS toxicity should be suspected. **Box 1** shows ECG changes in patients taking CAS.

Acute Toxicity

The arrhythmias of CAS are characterized by a depressed AV node and sensitized myocardium and often unresponsive to atropine. An asymptomatic period of minutes to hours may occur after a single toxic dose of CAS. Initially, there can occur symptoms such as nausea, vomiting, and/or abdominal discomfort which may be accompanied by CNS effects such as confusion, somnolence, and weakness due to hemodynamic changes. If GI symptoms recur after several hours, then the possibility of CAS toxicity is less. Hyperkalemia is rarely high enough to cause clinical toxicity. It is also an important



FLOWCHART 1: Cardioactive steroids.

BOX 1: ECG changes in patients taking cardioactive steroids.

- Sinus bradycardia
- Atrial fibrillation or flutter with slow ventricular response
- Atrial tachycardia with high-grade atrioventricular block
- Bidirectional ventricular tachycardia (pathognomonic)
- Premature ventricular contractions (most common finding)
- Ventricular tachycardia
- Ventricular fibrillation
- "Scooped" T waves (suggestive of therapeutic use, not necessarily overdose)

(ECG: electrocardiogram)

BOX 2: Risk factors for chronic cardioactive steroid toxicity.

- Dehydration
- Change in renal function (remain unrecognized)
- Inappropriate dose adjustment in patients with renal insufficiency
- Drug–drug interactions (verapamil, quinidine amiodarone, etc.)
- Use of macrolide (decreased gut flora that normally metabolizes cardioactive steroids)

TABLE 1: Causes of false-positive digoxin levels and digoxin drug–drug interactions.

Medical conditions and drugs causing false-positive results of digoxin levels	*Drug–drug interactions of digoxin*
Poor renal clearance	Angiotensin-converting enzyme inhibitor
Pregnancy	Amiodarone
Acromegaly	Diltiazem
Hypothermia	Quinidine
Elevated bilirubin levels	Verapamil
Spironolactone	Carvedilol
	Spironolactone

prognostic feature and manifestation of acute toxicity. Acute digitoxin overdose with a potassium level above 5.5 mEq/L was also associated with 100% mortality before the introduction of specific antibody therapy.

Chronic Toxicity

Chronic toxicity may produce vague clinical presentation such as GI upset, drowsiness, headache, visual disturbance, and delirium. It is also associated with hyperkalemia like acute toxicity which is likely to increase mortality and digoxin antibody requirement. Bradyarrhythmias occurring later in acute and chronic toxicity are due to direct toxin action on myocytes rather than AV nodal blockade. Thus, they are often unresponsive to atropine. Ventricular dysrhythmias are more common in chronic toxicity than acute toxicity. Chronic toxicity may present with nonspecific symptoms such as weakness, anorexia, abdominal pain, and nausea/vomiting. Factors such as volume depletion, renal insufficiency, electrolyte abnormality, or drug–drug interactions result in chronic toxicity. **Box 2** shows risk factors for chronic digoxin toxicity. Neuropsychiatric symptoms are more common in chronic toxicity as compared to acute toxicity. They are confusion, drowsiness, delirium, hallucinations, photophobia, chromatopsia (purple or yellow halos around lights), and decreased visual acuity. When a patient presents with unexplained bradycardia, nausea, vomiting, history of congestive cardiac failure or atrial flutter or fibrillation, one must rule out CAS toxicity.

Diagnosis

Continuous cardiopulmonary monitoring and hemodynamics should be evaluated in all patients with suspected cardiovascular toxicity. A 12-lead ECG is obtained to QRS or QT interval widening. It is done in all patients. Chest radiograph, pulse oximeter, and serum biochemistry are also obtained. A change in blood glucose level may suggest coexistent BAA or CCA ingestion. Serum lactate is the most specific biomarker for end-organ injury in drug-induced shock. Acute CAS toxicity may elevate the serum potassium level. If a patient presents with hyperkalemia with normal renal function and bradycardia, one must rule out CAS toxicity and serum digoxin concentration may be useful. Empiric therapy may be needed in patients having significant toxicity so an emergent digoxin assay could be performed. Digoxin is absorbed and distributed over many hours so while interpreting its concentration, it is important to consider the timing of ingestion. A serum concentration of >2 ng/mL suggests significant digoxin toxicity. So a digoxin concentration is assessed no sooner than 6 hours after ingestion except in pediatric poisoning and in suicidal cases. In nondigoxin cardioactive poisoning, interpretation of serum digoxin is a challenging task. Endogenous digoxin such as immunoreactive substances may be responsible for false-positive results as they are similar in structure and function to exogenous CAS (**Table 1**).

Management

Early GI decontamination and pharmacologic treatment should be started before the patient becomes unstable. All patients should be evaluated promptly and carefully monitored even if the vital signs are normal. All patients with hypotension should be given a crystalloid fluid bolus of 10–20 mL/kg or repeated as required. Volume depletion and renal insufficiency are the main causes of chronic CAS toxicity. *Digoxin-specific antibody treatment*: Unstable patients with acute life-threatening dysrhythmias require emergent empiric treatment with digoxin-specific antibody fragments. Since these patients have life-threatening toxicity of CAS, digoxin-specific antibody fragment administration is definitive therapy (**Box 3**). The total digoxin load will determine the dose of fab (**Table 2**). Hyperkalemia is a major complication of digoxin-specific antibody fragment. It should be corrected before giving the dose (**Box 4**).

BOX 3: Indications for digoxin-specific antibody fragments.

- Digoxin ingestion of 10 mg or more in an adult (4 mg in a child)
- Any potential cardioactive steroid dysrhythmia
- Brady dysrhythmia refractory to atropine
- Chronic poisoning with end-organ manifestations (e.g., altered mental status, gastrointestinal distress, renal impairment)
- Nondigoxin cardioactive steroids poisoning
- Hyperkalemia exceeding 5 mEq/L in acute digoxin toxicity
- Shock or hemodynamic instability
- Digoxin concentration* ≥15 ng/mL at anytime or ≥10 ng/mL after 6 h of ingestion

*To convert mmol/L to ng/mL, multiply by 0.78 (digoxin concentrations are reported in mmol/L by few laboratories).

TABLE 2: Dosing of digoxin-specific antibody fragments.*

Clinical picture	*Dose*
Acute toxicity, empiric dosing	10–20 vials (adult or pediatric)
Chronic toxicity, empiric dosing	3–6 vials (adult), 1–2 vials (child)
Ingested digoxin dose is known	$\text{Vials} = \frac{\text{Amount ingested (mg)} \times 0.8}{0.5 \text{ (mg per vial)}}$
Serum digoxin concentration† is known	$\text{Vials} = \frac{[\text{digoxin concentration (ng/mL)} \times (\text{weight (kg)}]}{100}$

*Each vial binds ~0.5 mg digoxin.

†To convert mmol/L to ng/mL, multiply by 0.78 (digoxin concentrations are reported in mmol/L by few laboratories).

Intravenous phenytoin can also be used in symptomatic supraventricular tachycardia in a dose of 100 mg bolus and can be repeated after 5 minutes. Though phenytoin and lidocaine are second-line drugs for the management of ventricular tachyarrhythmias, they can rarely be used as first-line drugs while fab is being procured/prepared or in some extreme situation. The dose of lidocaine in ventricular dysrhythmias is 1.5 mg/kg IV bolus which is followed by continuous infusion at a rate of 2.5–4 mg/min in adults and 50 μg/kg/min in children. In some cases where dysrhythmias are refractory to lidocaine and phenytoin, amiodarone can be used. Magnesium is also useful in some refractory cases (IV 1.5 g given over 20 min). If cardioversion is required, it should be done using low energy levels (20–100 J).

Management of Dyselectrolytemia

Hypokalemia is treated with supplemental potassium to achieve a level of >4 mEq/L. Hyperkalemia is treated by using insulin—glucose, bicarbonate, or exchange resins, and hemodialysis is used in renal failure and refractory cases. β-agonists may precipitate tachyarrhythmias so they should be avoided. Hypomagnesemia may occur in patients having chronic CAS poisoning which is associated with diuretic use. Myocardial irritability is reduced by the correction of the magnesium level. Transcutaneous and transvenous pacing is not likely to be beneficial in dysrhythmias caused by CAS poisoning. CAS have a large volume of distribution and high protein binding so hemodialysis and hemoperfusion are not effective in the elimination of these drugs.

BOX 4: Complications of digoxin-specific antibody fragments.

- Acute hypokalemia (severe hypokalemia should be treated before administration)
- Allergic reaction (allergies to papaya extracts or papain can also increase the risk)
- Rarely rapid atrial fibrillation after digoxin removal may occur
- Acute decomposition of underlying congestive cardiac failure

ANTIHYPERTENSIVE

Antihypertensive agents are ACE inhibitors, angiotensin II receptor blocker, CCA, sympatholytic drugs (α-adrenergic antagonists), BAA, adrenergic neuron-blocking agents, centrally acting agents, ganglion blocking agents, vasodilators (arterial, venous), and diuretics.

Angiotensin-converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors are mostly used for hypertension. They act on peptidyl dipeptide carboxyl hydrolase enzyme and inhibit the conversion of angiotensin I to angiotensin II in the lung and vascular endothelium. Adverse effects include cough, hypotension, bronchospasm, proteinuria, renal insufficiency, pancreatitis, and angioneurotic edema.

A patient may remain asymptomatic. Other features are hypotension, renal failure, and hyperkalemia.

Discontinue the offending agent and substitute with an alternative drug, activated charcoal.

Hypotension: IV colloids/crystalloids—10–20 mL/kg isotonic fluid. If not controlled, dopamine/noradrenaline can be used. For patients unresponsive to volume and pressor infusion, angiotensin is used in a dose of 8.5–18 μg/min with infusion. Naloxone is also used in the treatment of hypotension caused by ACE inhibitor overdose. In a patient with angioedema, early endotracheal intubation should be considered along with adrenaline, corticosteroids, and diphenhydramine. Sodium cromoglycate is given for the cough induced by ACE inhibitors. Hemodialysis may be beneficial.

Angiotensin II Receptor Blocker

It acts as an antagonist at angiotensin II receptors and thus inhibits its effects. Cough and angioneurotic edema do not occur with them as the bradykinin pathway is not affected, e.g., losartan/valsartan. Adverse effects include azotemia, oliguria in cases of congestive heart failure, and renal artery stenosis as the renal function depends on the function of the renin–angiotensin aldosterone system. Hepatotoxicity, which is reversible, is found. Clinical features include tachycardia/bradycardia, hypotension, and hyperkalemia. Vagal stimulation is the reason for bradycardia. Management consists of symptomatic and supportive treatment including cardiac

and hemodynamic monitoring, intravenous fluid resuscitation with crystalloids.Vasopressors are used in refractory cases not responding to crystalloids. Hemodialysis is ineffective as most agents are highly protein bound.

Calcium Channel Antagonists and β-adrenergic Antagonists

They have been discussed previously.

Sympatholytic Drugs

Alpha-adrenergic Antagonists

Alpha-1 adrenergic receptors are selectively blocked, e.g., prazosin, terazosin, phentolamine, tamsulosin, phenoxybenzamine, indoramin, tolazoline, and urapidil.

Adverse effects include palpitation, dizziness, vomiting, abdominal pain, and diarrhea which may occur when a large amount is ingested orally. Terazosin may cause headache or asthenia. Indoramin overdose can cause seizures. Priapism is also reported in some cases. Management is largely conservative and supportive includes intravenous fluids,vasopressors (noradrenaline preferred over dopamine). Priapism is a surgical emergency and require immediate urology consultation.

Centrally Acting Agents

Clonidine

Clonidine is an imidazoline compound having potent α_2-adrenergic activity. Besides its use in hypertension, it is also used in conditions such as opiate, ethanol, and nicotine withdrawal, migraine prophylaxis, and attention deficit disorder. Adverse effects include drowsiness, dry mouth, insomnia, orthostatic hypotension, agitation, myalgia, arrhythmias, and GI upset. Paralytic ileus may occur. Avoid abrupt withdrawal of clonidine as it can be life-threatening. Overdoses cause bradycardia which may progress to heart block hypotension, hypothermia, CNS depression, miosis, and periodic apnea. Paradoxical hypertension may occur sometimes. Hypothermia may occur within 1 hour of the ingestion and may last up to 48 hours. It is usually mild and resolves spontaneously within 6–8 hours.

All patients with an altered mental status, bradycardia, and hypo- or hypertension require close observation for frequent monitoring of the vital signs for a minimum period of 6–12 hours or until the patient remains asymptomatic for 4 hours. GI decontamination with activated charcoal is beneficial.

Bradycardia and hypotension may be responsive to only atropine in patients with heart rate below 60/min. In case of hypotension, give 10–20 mL/kg isotonic fluid. In persistent hypotension, use dopamine or noradrenaline. IV infusion of sodium nitroprusside is given at a rate of 0.5–10 μg/kg/min for paradoxical hypertension. Tolazoline (α-adrenergic antagonist) can be used in a dose of 5–10 mg as an IV infusion every 15 minutes (maximum dose 40 mg). Naloxone is used to reverse the deleterious effect on respiration and cardiovascular system function. It is also helpful in lessening the "paradoxical hypertension" effect and least effective in hypotension. The initial dose of naloxone for opiate overdose is 0.4–2 mg IV bolus (in both adults and children) and it is repeated at 2–3-minute interval according to the response. It should be administered cautiously in pediatric patients as it will cause hypertension in them which is treated by phentolamine. Hemodialysis, hemoperfusion, and forced diuresis are not likely to enhance the elimination of clonidine.

Methyldopa

Methyldopa is an antihypertensive whose specific mechanism of action is not clear. To lower blood pressure, it acts centrally via α-methylnoradrenaline which is an active metabolite.

Methyldopa can cause hemolytic anemia, pancreatitis, hepatitis, and myocarditis. Other features include headache, drowsiness, depression, edema, bradycardia, nightmares, nasal stuffiness, sexual dysfunction, galactorrhea, gynecomastia, and dry mouth. A positive Coombs test is found in about 20% of patients. Acute overdose of methyldopa can lead to severe hypothermia, nausea, vomiting, dry mouth, dizziness, weakness, bradycardia, lethargy, coma, paresthesia, headache, involuntary movements, and psychic disturbance. All patients should be admitted and treated in the intensive care unit. Fluid resuscitation should be started in hypotensive patient with 10–20 mL/kg isotonic fluid. Bradycardia can be treated with atropine. Hemodialysis and hemoperfusion may be beneficial in severe poisoning refractory to traditional therapy.

Vasodilators

Sodium Nitroprusside

Sodium nitroprusside has a vasodilatory effect due to the release of nitric oxide after being metabolized in red blood cells (RBCs). Cyanide is also released which can cause significant toxicity in presence of renal insufficiency or low thiosulfate stores (critically ill patients, infants, malnourished). It is used in the treatment of hypertensive emergencies and to induce controlled hypotension during anesthesia to reduce bleeding in surgical procedures. It is also used in congestive cardiac failure.

At a high rate of infusion, there is restlessness, anxiety, muscle twitching, and diaphoresis. When the rate of infusion of sodium nitroprusside is >5 μg/kg/min, toxic accumulation of cyanide with severe lactic acidosis can occur. Concomitant administration of sodium thiosulfate can prevent this. The risk factors for the development of nitroprusside toxicity are renal impairment, hypoalbuminemia, cardiopulmonary bypass procedures, and moderate-to-high dose of nitroprusside administration.

Acute toxicity is characterized by vasodilation and hypotension which can be complicated by nausea, vomiting, headache, sweating, palpitation, and substernal discomfort. An increased cyanide level in the blood may lead to the development of severe acidosis. Thiocyanate may lead to the development of neurotoxic syndrome manifesting by toxic psychosis, hyperreflexia, confusion, weakness, tinnitus, seizure, and coma.

Immediate discontinuation of the infusion is required to control the hypotension caused by sodium nitroprusside which may be followed by IV fluid replacement and vasopressor support. Maintain high PO_2 by giving 100% oxygen. Sodium nitrite and sodium thiosulfate are given in patients having dyspnea, headache, and impaired mental

status. In acidotic patients, sodium bicarbonate is given IV 1 mEq/kg. Serial arterial blood gas (ABG) determines further administration of sodium bicarbonate. Hemodialysis is beneficial in correcting resistant acidosis and increasing thiocyanate clearance, thus helping thiosulfate–cyanide reaction to thiocyanate.

Hydralazine

Hydralazine causes direct relaxation of arteriolar smooth muscle but is not a dilator of capacitance vessels such as the coronary artery. It is used in the treatment of hypertensive emergencies in pregnancy.

Adverse effects include dizziness, headache, lacrimation, blurred vision, palpitation and tachycardia, myocardial ischemia, glomerulonephritis, serum sickness, and lupus syndrome. In slow acetylators, a lupus-like syndrome may develop after a long-term use of hydralazine in a dose of >400 mg/day. Decontamination, IV fluids, and noradrenaline are the choices if required. In patients having myocardial ischemia or persistent tachycardia, BAA and CCA can be used. Pyridoxine is given for peripheral neuropathy.

ANTIARRHYTHMICS

Antiarrhythmics are used to prevent life-threatening arrhythmias and maintain sinus rhythm. As they have a narrow therapeutic index, they promote arrhythmias and increase mortality. Only twice the daily dose can be lethal because of their potent modulation of cardiac electrical activity. The Vaughan–Williams classification of antiarrhythmic drugs is as follows:

- *Class I*: *Sodium channel blockers*
  - IA: Moderate to marked sodium channel blockade—Disopyramide, procainamide, quinidine
  - IB: Mild-to-moderate sodium channel blockade—Lignocaine, phenytoin, mexiletine, tocainide
  - IC: Marked sodium channel blockade—Encainide, flecainide, moricizine, propafenone
- *Class II*: *BAA*—Atenolol, esmolol, metoprolol, bretylium, and timolol
- *Class III*: *Potassium channel blockers*—Acecainide, bretylium, amiodarone, sotalol
- *Class IV*: CCA
- *Unclassified*: Adenosine

Sodium Channel Blockers

Electrocardiogram changes, such as QRS widening and ventricular dysrhythmias, should prompt the physician to consider the possibility of sodium channel blocker toxicity. A syncopal event (e.g., quinidine syncope) may be the clinical manifestation of transient ventricular dysrhythmia.

All classes of drugs can cause significant cardiovascular toxicity which includes AV blocks, bradyarrhythmia, ventricular dysrhythmias, hypotension, and asystole. Extracardiac effects include CNS toxicity including paresthesia, dizziness, ataxia, tremors, sedation, confusion, seizure, coma, and respiratory arrest. CNS toxicity warrants immediate cardiovascular system evaluation as it may occur before cardiovascular toxicity. Disopyramide antagonizes muscarinic receptors causing mydriasis, tachycardia, hyperthermia, delirium, anhidrosis, erythema, ileus, and urinary retention. Quinine and quinidine can cause cinchonism which includes loss of vision, vertigo, and hearing impairment as the retina and inner hair cells damage occur due to toxicity. Drugs of classes IA and IC can also affect pancreatic beta cells by blocking potassium channel and releasing insulin causing hypoglycemia. Some agents may cause immune-related hypersensitivity reaction where symptoms include fever, rash, hepatitis, and blood dyscrasias. Drug-induced lupus has been reported with procainamide, quinidine, and tocainide.

Potassium Channel Blockers

Patients taking potassium channel blockers for therapeutic use or an overdose are at increased risk of torsade de pointes as they increase the duration of QTc interval. Episodes may resolve spontaneously only causing syncope or may persist and degenerate to ventricular fibrillation and sudden death (**Table 3**).

Management

General management includes a focus on airway, breathing, and circulation. Continuous cardiopulmonary monitoring is advised in all patients having antidysrhythmic toxicity. ECG should be done as early as possible. Decontamination with activated charcoal is beneficial. All patients with severe sodium channel blocking (defined as QRS > 120 ms, bradyarrhythmia, or hypotension) should be given sodium bicarbonate. Serum pH of 7.50–7.55 should be maintained. Sodium bicarbonate treatment causes kaliuresis and hypokalemia which in turn lead to difficulty in serum alkalinization. Hypokalemia also increases QTc interval and contributes to toxicity. So it is avoided to replace potassium liberally. Sodium lactate may also be useful. Dose of sodium bicarbonate is 1–2 mEq/kg IV bolus. Repeat as required to reverse QRS widening and dysrhythmia. Maintain an arterial pH 7.4–7.55.

Acidosis caused by seizures can potentiate cardiotoxicity, so it should be treated aggressively by using benzodiazepines, barbiturates, and propofol. In case of hypotension, give IV isotonic solution at a rate of 10–20 mL/h. If hypotension persists, direct-acting vasopressors should be given. Advanced cardiovascular life support (ACLS) protocol with cardioversion, IV magnesium sulfate, electrolyte correction, and overdrive pacing is indicated for recurrent polymorphic ventricular

TABLE 3: Potassium channel blocker toxicity.

Drugs	*Effects*
Amiodarone	• Thyroid dysfunction • Pulmonary fibrosis • Corneal deposits • Decreased inotropy with intravenous dosing • Skin pigmentation • Hepatitis • Peripheral neuropathy
Bretylium	Hypotension preceded by the initial sympathomimetic effect
Dofetilide	Torsade de pointes
Ibutilide	• Atrioventricular block • Torsade de pointes

tachycardia. Isoproterenol infusion can also be used along with them as it decreases temporal dispersion of refractoriness.

In stable monomorphic ventricular tachycardia, lignocaine and amiodarone are the first-line therapy.

Dose of lignocaine is 1–1.5 mg IV bolus. An additional bolus can be given over 3–5 minutes for refractory ventricular tachycardia/ventricular fibrillation (VT/VF). The total dose is not to exceed 3 mg/kg or >200–300 mg during a 1 hour period. During cardiac arrest, only bolus therapy is advised. Begin maintenance infusion of 1–4 mg/min once the circulation has been restored. Repeat 0.5 mg/kg bolus if arrhythmias recur during infusion and increase the rate of infusion incrementally (maximum infusion rate is 4 mg/min). The pediatric dose is 1 mg/kg initial bolus intravenously followed by continuous infusion of 20–50 μg/kg/min. In case of disopyramide overdose, do not use procainamide or quinidine or bretylium.

Along with conventional supportive measures and CPR, high doses of calcium chloride (0.5 g slowly every 5 min up to a maximum of 3 g) are effective in reversing some of the cardiac effects.

In case of class IC overdose, class IA drugs (quinidine, procainamide, disopyramide) are relatively contraindicated because of cross-over in electrophysiologic properties. The class IC drugs are moderately refractory to traditional antiarrhythmic drug therapy and cardioversion/ventricular pacing.

In class IC overdose, class IB (lignocaine, phenytoin, mexiletine, tocainide) may be the best alternative based on the electrophysiologic properties but they can also exacerbate toxicity.

Acute lung injury may occur with disopyramide and it may be delayed up to 24–72 hours after exposure. Mechanical ventilation and positive end-expiratory pressure (PEEP) may be required if a high FiO_2 is needed. Hemodialysis and hemoperfusion are effective in enhancing the elimination of the drug.

Amiodarone (Class III: Potassium Channel Blocker)

Amiodarone primarily prolongs cardiac action potential without changing the resting membrane potential. Vasodilation occurs as a result of noncompetitive α and β antiadrenergic activity. Substantial overdose in a patient can lead to bradycardia/heart block, torsade de pointes, and hypotension. Adult respiratory distress syndrome may be rapidly progressive. Pulmonary toxicity (pulmonary fibrosis/interstitial pneumonitis) may occur causing cough, dyspnea, fever, chest pain, weight loss, and abnormal pulmonary function tests. Rapid IV infusion can cause hypotension, ventricular arrhythmias, bradycardia, and heart block. Hypo- or hyperthyroidism or both can occur. Hepatotoxicity, acute pancreatitis, epididymitis, peripheral neuropathy, blue-green color discoloration of skin and nails, corneal microdeposits, bone marrow granuloma may also occur.

Decontamination can be done up to several hours after ingestion. Only stomach wash is advised. Oral Cholestyramine (4 g/h for 4 h) may reduce the half-life of amiodarone. Corticosteroids are used in pulmonary fibrosis. ECG monitoring is important even after several days of ingestion. Isoprenaline and direct current (DC) cardioversion is done in case of severe cardiovascular collapse. Beta adrenergic agonists or pacemaker in a case of bradycardia. They are also beneficial in sinus arrest. Amiodarone-induced nonsustained polymorphic tachycardia is treated with IV $MgSO_4$. Vasopressors are used in hypotension. Hemodialysis and hemoperfusion are not beneficial.

Adenosine

Adenosine is a nucleotide found in all cells. It is released from myocytes under various physiological and pathological conditions. It is used effectively in the treatment of reentrant supraventricular tachycardia when administered as a rapid IV bolus. It is a degenerative product of adenosine triphosphate (ATP) which in itself may be associated with a higher incidence of adverse effects than adenosine. Significantly lower doses of adenosine should be used in patients receiving dipyridamole as it potentiates the effect of adenosine by competitively inhibiting the transport of adenosine into the cells. Methylxanthines are competitive antagonists of adenosine so they may not be effective in patients taking methylxanthines. Prolonged bradycardia may occur if adenosine is given to patients with CCA toxicity.

Symptomatic and supportive treatment is recommended. Theophylline can be used in prolonged chest pain in patients having ischemic heart disease. The adverse effect of adenosine can be reduced by using a smaller initial dose. Inosine can be used before ATP to alleviate its adverse effects.

SUMMARY

Cardiovascular drugs are used widely in cardiovascular diseases and are among the most significant determinants of morbidity and mortality in the entire world. Because of the widespread use of these drugs, their overdose is also common. Mostly, the overdose is unintentional but the intentional use is not uncommon. The proportion of intentional overdose is also significant typically in younger population with less burden of cardiovascular disease. Sudden cardiac death in a young healthy person is most likely to be drug-related. Poisoning is the leading cause of cardiac arrest in patients younger than 40 years of age but infrequent in elderly patients. To manage these patient's proper assessment of hemodynamic status remains important so that pathophysiological derangement can be dealt with effective therapy. Extracorporeal support, e.g., intraaortic balloon pump cardiac bypass can be added in cases of severe toxicity and refractory to medical therapy.

Salicylates, Acetaminophen, and Nonsteroidal Anti-inflammatory Drugs

209 CHAPTER

Ajay K Mishra, Jitendra Chandrakar

INTRODUCTION

Salicylates, acetaminophen (APAP), and nonsteroidal anti-inflammatory drugs (NSAIDs) are few of the common over-the-counter drugs used for relieving pain and fever. These drugs are also available in various combinations with other medicines, and their ease of availability makes them one of the most common among drug overdose and toxicity.

MECHANISM OF ACTION

All these drugs act as inhibitors of the cyclooxygenase enzyme responsible for prostaglandin synthesis, thus preventing prostaglandin-mediated inflammation and fever. APAP and NSAIDs are reversible inhibitors while salicylates cause irreversible inhibition of cyclooxygenase.

SALICYLATES

Salicylates are widely used all over the world for their anti-inflammatory, antipyretic, analgesic, and antiplatelet properties. *Aspirin is the most widely used salicylate* found in almost every other household.

Pharmacology

Salicylates are rapidly absorbed from the gastrointestinal (GI) tract and peak absorption occurs within 2–4 hours with serum concentration remaining elevated for >12 hours following an overdose in large quantity. Salicylates conjugate with glucuronic acid and glycine in the liver. Free salicylic acid and conjugated forms get eliminated by the kidney. Salicylates follow first-order kinetics at therapeutic concentrations while at serum concentration > 30 mg/dL, it follows zero-order kinetics.

In case of overdose, the kinetic changes from first order to zero order; hence, the metabolic rate becomes constant. Absorption is delayed due to aspirin-induced pylorospasm and formation of bezoar in the stomach. With elevated concentrations, the volume of distribution increases and protein binding decreases, resulting in more amount of free drug reaching the tissues. Saturation of the hepatic metabolic pathways and pH-dependent urinary excretion of salicylate leads to an increase in the half-life of salicylates at toxic concentrations.

Toxic dose: 200–300 mg/kg
Lethal dose: ≥500 mg/kg

Pathophysiology

- Salicylates stimulate the medullary respiratory centers causing hyperventilation and respiratory alkalosis.
- They mainly impair cellular respiration by inhibiting Kreb's cycle and uncoupling of oxidative phosphorylation, thus increasing the production of lactic acid causing metabolic acidosis. This decrease in pH causes an increase in the unionized form of the drug which can then easily cross the cell membranes and blood–brain barrier.
- They impair the glucose metabolism causing hypoglycemia and sometimes hyperglycemia.
- There is significant potassium loss because of vomiting, increased renal excretion, and inhibition of the active transport system.
- Salicylates also cause pulmonary and cerebral edema, the exact mechanism of which is not known.

Clinical Features

The patient may present initially with nausea, vomiting, tinnitus, impaired hearing, hyperventilation, and hyperthermia. Subsequently, the patient may develop severe dehydration. With an increase in acidemia, the patient develops central nervous system (CNS) symptoms, e.g., altered mental status, seizures, or coma.

Investigations

- Serum salicylate concentration should be measured after 6 hours of consumption, followed by a second sample after 2 hours to look for a serial rise in concentration which is indicative of continued absorption. A serum concentration of >100 mg/dL is associated with high mortality and is an indication for hemodialysis.
- Renal function test—to look for renal impairment

- Serum potassium
- Prothrombin time (PT) and international normalized ratio (INR)—to look for coagulopathy due to hepatotoxicity
- Blood gas analysis—to know the acid–base status, anion gap, and lactate levels and to guide the treatment
- An ECG—to look for changes due to hypokalemia.
- Chest X-ray—to look for pulmonary edema
- CT/MRI brain—if the patient presents with CNS symptoms

Management

Treatment objectives include cardiorespiratory stabilization, prevention of absorption, correction of acid–base abnormalities and fluid deficits, and increasing the elimination and excretion.

- Rapid assessment and stabilization of airway, breathing, and circulation
- Intubation should be avoided as it may worsen the toxicity and should be reserved only for patients with respiratory failure.
- Hypotensive and severely dehydrated patients should be aggressively hydrated with IV fluids. If the patient does not respond to fluid resuscitation, then vasopressors may be considered.
- *Gastric decontamination:* Gastric lavage is useful if done within 1 hour of ingestion. To reduce the absorption, activated charcoal should be given as early as possible. Due to delayed gastric emptying in salicylate overdose, repeated doses of activated charcoal can be given to prevent continued absorption.

  Whole bowel irrigation (WBI) is advisable for toxic doses of enteric-coated or sustained-release drugs, especially when such patients present >2 hours after ingestion when activated charcoal is not much effective.
- Dextrose should be given for hypoglycemia or to prevent neuroglycopenic symptoms in euglycemic patients.
- *Serum and urinary alkalization:* Alkalization therapy by using sodium bicarbonate remains the mainstay of treatment in salicylate toxicity. Sodium bicarbonate causes ion trapping, i.e., it increases the serum pH, thus ionizing more drug in the serum and subsequently decreasing tissue distribution. Sodium bicarbonate also alkalinizes the urine and hence prevents reabsorption of ionized salicylate in the kidneys and increases its excretion. An initial bolus of 1–2 mEq/kg should be administered followed by an infusion of 100–150 mEq in 1 L of sterile water with 5% dextrose at 1.5–2 times the maintenance dose of IV fluids. The target is to maintain a serum pH of 7.45–7.55 and a urine pH of 7.5–8. Alkalization should be continued till (1) serum salicylate level is <40 mg/dL, (2) serum pH has returned to the normal level, (3) metabolic acidosis has resolved, and (4) the patient is asymptomatic.
- Hypokalemia, if present, should be corrected and prevented for alkalization therapy to be effective.
- *Hemodialysis:* The indications of hemodialysis in salicylate poisoning are as follows:
  - Serum salicylate concentration > 90 mg/dL
  - pH ≤ 7.20
  - Altered mental status
  - Cerebral and/or pulmonary edema
  - Fluid overload
  - Renal failure

Disposition

Patients who have CNS symptoms, pulmonary edema, dehydration, acidosis, electrolyte imbalance, renal dysfunction, or increasing serum salicylate levels during repeated testing should be admitted to a hospital, preferably in the critical care unit. Patients can be discharged only if asymptomatic or serum salicylate levels are on decreasing trends.

ACETAMINOPHEN

Acetaminophen (chemical name: N-acetyl-para-aminophenol) or *paracetamol* is the 25th most commonly prescribed drug worldwide for pain and fever. APAP toxicity, due to either intentional ingestion or therapeutic misadventure, is one of the leading causes of hepatic failure and mortality in the USA.

Pharmacology

Acetaminophen is rapidly absorbed mainly in the small intestine with peak plasma concentrations reaching within 1 hour and complete absorption within 4–5 hours of ingestion. The therapeutic dose of APAP is 10–15 mg/kg/dose in children (up to a maximum of 75 mg/kg/day) and 325–1,000 mg/dose in adults every 4–6 hours (not to exceed 4,000 mg/day). Therapeutic concentration ranges between 10 and 20 µg/mL. Elimination half-life is usually 2–4 hours. Toxicity occurs usually after a single dose of ≥150 mg/kg or in multiple staggered doses.

Pathophysiology

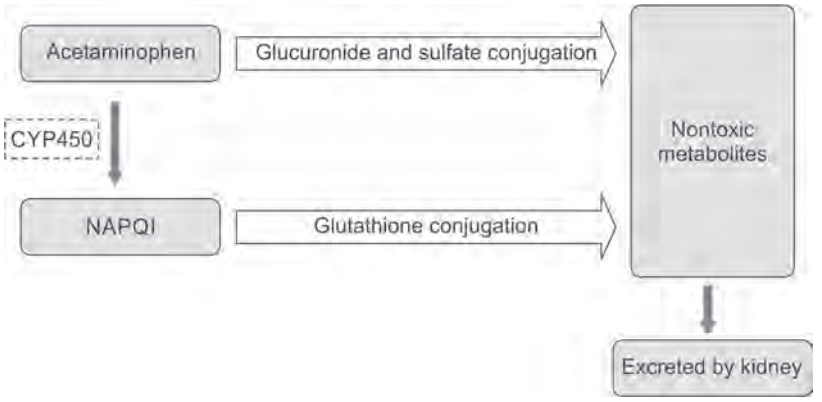
At a therapeutic dose, around 90% of APAP is metabolized in the liver and around 2–3% is excreted unchanged in the urine. The rest of the metabolism takes place via the cytochrome P450 oxidase pathway and gets converted to a toxic metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI). This NAPQI gets conjugated with glutathione to form nontoxic metabolites which are excreted in urine (**Fig. 1**).

In case of overdosage, the glucuronide and sulfates get saturated and more of NAPQI is produced. With the depletion of glutathione stores in the liver due to excess of NAPQI, the concentration of toxic metabolite NAPQI increases leading to liver damage and hepatic necrosis (**Fig. 2**).

Patients taking substances or medications that induce the cytochrome P450 system (alcohol, anticonvulsant, or antituberculous drugs) or those with glutathione depletion (poor nutrition, alcoholics, and acquired immunodeficiency syndrome patients) are at an increased risk of hepatic toxicity. The clinical features of APAP toxicity have been divided into four stages (**Table 1**).

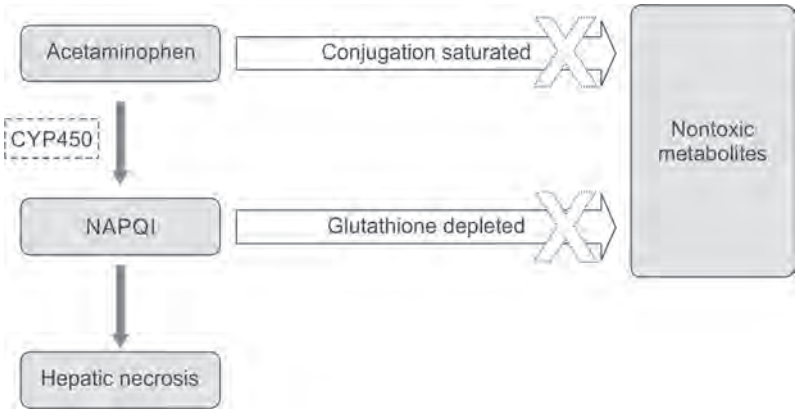
Investigations

- Serum APAP concentration—should be obtained 4 hours after ingestion
- Liver function tests (LFT)—may not be abnormal until >18 hours after the overdose. Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are the most sensitive markers of liver damage.
- INR—a very sensitive marker of liver damage and the best prognostic parameter



(NAPQI: *N*-acetyl-*p*-benzoquinone imine)

FIG. 1: Metabolism of acetaminophen at therapeutic dose.



(NAPQI: *N*-acetyl-*p*-benzoquinone imine)

FIG. 2: Metabolism of acetaminophen at toxic dose.

TABLE 1: Clinical features of acetaminophen toxicity.

Stages	*Time course*	*Clinical manifestations*	*Laboratory abnormalities*
Stage 1	<24 h	Asymptomatic or anorexia, nausea, vomiting	Hypokalemia
Stage 2	2–3 days	• Improvement in anorexia, nausea, and vomiting • Abdominal pain, hepatic tenderness, jaundice	Elevated serum transaminases, elevated bilirubin, and prolonged prothrombin time if severe
Stage 3	3–4 days	• Recurrence of anorexia, nausea, and vomiting • Encephalopathy, anuria, jaundice	Hepatic failure, metabolic acidosis, coagulopathy, renal failure, pancreatitis
Stage 4	>4 days	Clinical improvement and recovery (7–8 days) or deterioration to multiorgan failure and death	Improvement and resolution or continued deterioration

- Renal function—creatinine is a useful prognostic marker and low urea may suggest malnutrition and therefore glutathione depletion.
- Blood sugar levels—to look for hypoglycemia
- Blood gas analysis—to check for acid–base disturbances. Metabolic acidosis, if present, is a poor prognostic sign.

Management

Treatment objectives include supportive care, prevention of drug absorption, and administration of an antidote.

- Rapid assessment and stabilization of airway, breathing, and circulation
- *Gastric decontamination*: Gastric lavage is useful if done within 1–2 hours of ingestion. To reduce the absorption, activated charcoal should be given within 4 hours of ingestion if no contraindications are present.
- Antiemetics should be given to control nausea and vomiting.
- *Antidote*: *N-acetylcysteine (NAC) is the antidote for APAP toxicity*. It binds to the toxic metabolite NAPQI and prevents hepatic damage.
  The IV dosing schedule is as follows:
  - 150 mg/kg in 200 mL of 5% dextrose over 1 hour, followed by

- 50 mg/kg in 500 mL 5% dextrose over 4 hours, followed by
- 100 mg/kg in 1,000 mL 5% dextrose over 16 hours

The oral dosing schedule is as follows:

- 140 mg/kg PO as a loading dose, followed by
- 70 mg/kg PO every 4 hours for a total of 17 doses

N-acetylcysteine can cause side effects ranging from local erythema and urticaria around the infusion site to angioedema or life-threatening anaphylaxis. If anaphylaxis occurs, the infusion should be stopped immediately and anaphylaxis should be treated. Once anaphylaxis settles, the entire dose of acetylcysteine may then be administered, possibly at a slower rate of infusion (e.g., at a rate of 50 mg/kg/h) or by the oral route regimen.

The timing of the overdose decides the treatment to be followed in case of APAP toxicity (**Table 2**). Paracetamol treatment nomogram (*Rumack–Matthew nomogram*) should be used to interpret the measured serum paracetamol levels. NAC should be continued if (any one of the following):

- Paracetamol level is on or above the treatment line between 4 and 15 hours after a single ingestion.
- Serum paracetamol is still detectable 15 hours after single ingestion.
- Serum paracetamol is detectable 4 hours after uncertain time of ingestion.
- INR > 1.3
- ALT > 53 IU/L

Liver transplantation: It is needed in patients with severe APAP -induced liver injury which not improving by NAC and supportive care. The Modified Kings College Criteria for paracetamol toxicity are used to identify patients who may require transplantation:

- pH < 7.3 or
- Arterial lactate >3.5 mmol/L after 4 hours of early fluid resuscitation or arterial lactate >3.0 mmol/L after 12 hours of fluid resuscitation, or
- PT > 100 seconds (INR > 6.5), and
- Creatinine > 300 μmol/L, and
- Grade 3 or 4 hepatic encephalopathy

Disposition

Patients who are asymptomatic and fit into the criteria for treatment with NAC can be admitted to the emergency observation unit or ward. Patients with severe hepatotoxicity or having a risk of fulminant hepatic failure should be treated in the intensive care unit.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs are a group of drugs having anti-inflammatory, analgesic, and antipyretic properties. They are classified as nonselective cyclooxygenase (COX) inhibitor (traditional NSAIDs) or selective COX-2 inhibitor.

Pharmacology

NSAIDS get completely absorbed from the upper small intestine and within 1–2 hours reach peak serum levels. They are weak acids, tightly bound to plasma proteins, and thus have a low volume of distribution (0.1–0.2 L/kg). NSAIDs are metabolized by hepatic transformation, mainly oxidation and glucuronidation, and excreted in the urine. Their elimination half-lives vary from short acting (<6 h, e.g., ibuprofen, diclofenac, ketoprofen, indomethacin) to long acting (>6 h, e.g., naproxen, celecoxib, piroxicam).

Clinical Features

Most of the patients with NSAIDs overdose remain asymptomatic and very few patients show minor CNS or GI symptoms, e.g., nausea, vomiting, drowsiness, blurred vision, and dizziness.

TABLE 2: Management of acetaminophen poisoning according to timing.

Timing	*Total dose*	*Investigation*	*Management*
Single ingestion in <1 h	>150 mg/kg	Delay blood sampling until 4 h postingestion	Activated charcoal (50 g orally), IV antiemetic, admit for observation while sampling awaited at 4 h
Single ingestion in >1 h but <4 h	>150 mg/kg	Delay blood sampling until 4 h postingestion	Activated charcoal (50 g orally), IV antiemetic, admit for observation while sampling awaited at 4 h
Single ingestion in >4 h but <8 h	<150 mg/kg	Blood sampling for serum paracetamol level	If the result is expected to be available before 8 h of ingestion, treatment should be guided by the result
	>150 mg/kg	Blood sampling for serum paracetamol level	If the result is not expected to be available before 8 h, NAC should be started immediately without waiting for the result
Single ingestion 8–24 h	<150 mg/kg	Blood sampling for serum paracetamol level	Treatment should be guided by the result
	>150 mg/kg	Blood sampling for serum paracetamol level	NAC should be started immediately without waiting for the result
Single ingestion >24 h	>150 mg/kg	Blood sampling for serum paracetamol level	NAC should be started immediately without waiting for the result
Timing unclear or ingestion is staggered		Blood sampling for serum paracetamol level	Treatment should be started immediately without waiting for the result

(NAC: N-acetylcysteine)

The most commonly ingested NSAID in overdose is ibuprofen. Usually, minor toxicity is seen in ingestion of doses >100 mg/kg whereas significant clinical toxicity is seen after ingestion of massive overdose, i.e., >400 mg/kg. Massive ingestions (particularly ibuprofen and naproxen) can cause high anion gap metabolic acidosis resulting in cardiac dysrhythmias and electrolyte abnormalities.

Acute kidney injury and renal papillary necrosis can result after a massive overdose and are more prone in patients with protracted hypovolemia and hypotension. This renal dysfunction is usually reversible and improve with supportive measures.

Central nervous system effects range from drowsiness to coma. Seizures are seen in many NSAIDs overdose, e.g., ibuprofen, diclofenac, indomethacin, and mefenamic acid.

Indomethacin overdose can cause hematological toxicity, e.g., aplastic anemia and agranulocytosis. NSAIDs can also cause allergic reactions ranging from urticaria to anaphylaxis.

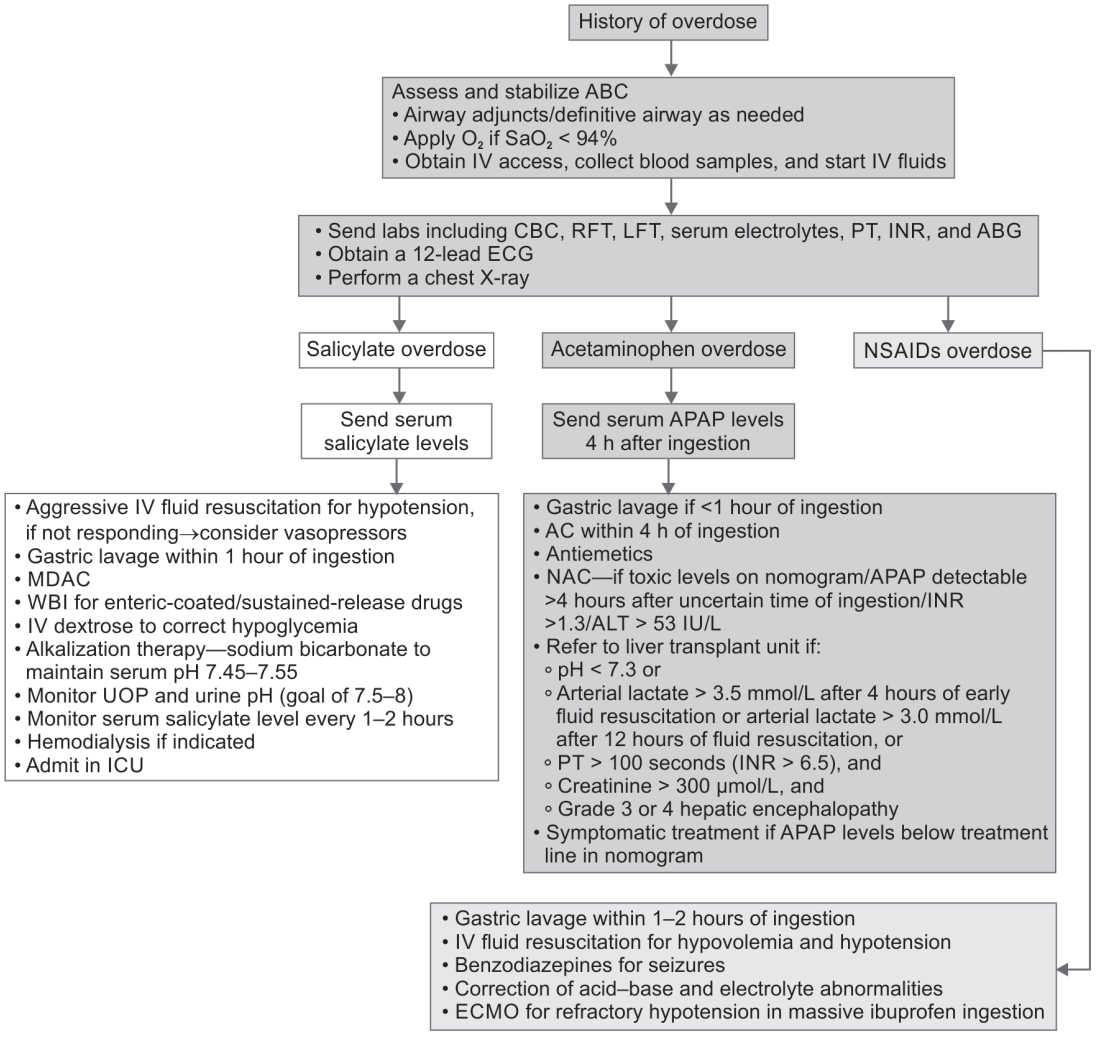
Investigations

- Blood gas analysis to rule out acid–base abnormalities and electrolyte disturbances
- ECG to look for any dysrhythmias
- Renal function test to assess renal dysfunction
- Serum NSAIDs levels are not of much use, but serum salicylates and APAP levels should be checked to rule out coingestions.
- Brain imaging, if indicated according to clinical history, to rule out other causes of CNS symptoms

Management

Management of NSAIDs overdose is usually supportive and no specific antidotes are available.

- Rapid assessment and stabilization of airway, breathing, and circulation



History of overdose
Assess and stabilize ABC
• Airway adjuncts/definitive airway as needed
• Apply O_2 if SaO_2 < 94%
• Obtain IV access, collect blood samples, and start IV fluids
• Send labs including CBC, RFT, LFT, serum electrolytes, PT, INR, and ABG
• Obtain a 12-lead ECG
• Perform a chest X-ray
Salicylate overdose
Acetaminophen overdose
NSAIDs overdose
Send serum salicylate levels
Send serum APAP levels 4 h after ingestion
• Aggressive IV fluid resuscitation for hypotension, if not responding→consider vasopressors
• Gastric lavage within 1 hour of ingestion
• MDAC
• WBI for enteric-coated/sustained-release drugs
• IV dextrose to correct hypoglycemia
• Alkalization therapy—sodium bicarbonate to maintain serum pH 7.45–7.55
• Monitor UOP and urine pH (goal of 7.5–8)
• Monitor serum salicylate level every 1–2 hours
• Hemodialysis if indicated
• Admit in ICU
• Gastric lavage if <1 hour of ingestion
• AC within 4 h of ingestion
• Antiemetics
• NAC—if toxic levels on nomogram/APAP detectable >4 hours after uncertain time of ingestion/INR >1.3/ALT > 53 IU/L
• Refer to liver transplant unit if:
◦ pH < 7.3 or
◦ Arterial lactate > 3.5 mmol/L after 4 hours of early fluid resuscitation or arterial lactate > 3.0 mmol/L after 12 hours of fluid resuscitation, or
◦ PT > 100 seconds (INR > 6.5), and
◦ Creatinine > 300 µmol/L, and
◦ Grade 3 or 4 hepatic encephalopathy
• Symptomatic treatment if APAP levels below treatment line in nomogram
• Gastric lavage within 1–2 hours of ingestion
• IV fluid resuscitation for hypovolemia and hypotension
• Benzodiazepines for seizures
• Correction of acid–base and electrolyte abnormalities
• ECMO for refractory hypotension in massive ibuprofen ingestion

(AC: activated charcoal; ABC: airway, breathing circulation; ABG: arterial blood gas; APAP: acetaminophen; CBC: complete blood count; ECG: electrocardiogram; ECMO: extracorporeal membrane oxygenation; ICU: intensive care unit; INR: international normalized ratio; IV: intravenous; LFT: liver function test; MDAC: multiple-dose activated charcoal; NAC: N-acetylcysteine; NSAIDs: nonsteroidal anti-inflammatory drugs; PT: prothrombin time; RFT: renal function test; UOP: urine output; WBI: whole bowel irrigation)

FLOWCHART 1: Summary: Algorithm for salicylates acetaminophen NSAIDs toxicity.

- Although very little evidence is available, gastric lavage and activated charcoal may be considered for massive overdosage presenting within 1–2 hours of ingestion.
- In case of hypovolemia and hypotension, rapid IV crystalloid infusion should be given.
- Acid–base abnormality and dyselectrolytemia should be corrected through supportive measures.
- Seizures should be treated with benzodiazepines.
- Extracorporeal membrane oxygenation can be considered for refractory hypotension in case of massive ibuprofen ingestion.

Disposition

Patients with small ingestions, <100 mg/kg, and asymptomatic can be discharged from the emergency room after giving primary supportive therapy. Patients with massive ingestions, >400 mg/kg, suspected coingestions of salicylates or APAP, acid–base abnormalities, or CNS symptoms will require hospitalization for further management.

SUMMARY

Salicylates, APAP, and NSAIDs are the common drugs which are available over the counter and used for relieving pain and fever. These drugs are also available in various combinations with other medicines, and their ease of availability makes them one of the most common among drug overdose and toxicity. The emergency physician should be aware of the clinical features of their toxicity and guideline for the management (**Flowchart 1**).

210 CHAPTER

Hydrocarbons and Volatile Substances

Atanu B Bhattacharya

INTRODUCTION

Hydrocarbons are a group of organic compounds having carbon and hydrogen elements. It is the basis of many structures, from plants to vegetables which are consumed, and of various substances derived from petroleum such as fuels, polymers, various oils, and solvents and used in the manufacturing of drugs and dyes. Some of the compounds are in a liquid form while some in a gaseous form and some are volatile in nature at room temperature and pressure while others are converted by the combustion process. The state of the hydrocarbon is determined by the length of its chain and its branching. Compounds of hydrocarbon that get converted to a gaseous state are termed *volatile organic compounds* (VOCs). Benzene, toluene, xylene, and tetrachloroethylene are a few common VOCs. They can create petrochemical smog in the environment and are potentially toxic and carcinogenic. *Most of the VOCs are mixed hydrocarbons and abused by sniffing, huffing, and bagging*. Substances being commonly abused as volatile substances are fuels and solvents.

CLASSIFICATION AND PROPERTIES

Hydrocarbons are classified on the basis of their structure: (1) Acyclic or aliphatic, which are then divided into alkanes (C_nH_{2n+2}), alkenes (C_nH_{2n}), and alkynes (C_nH_{2n-2}); (2) Aromatic hydrocarbons (arenes) (**Table 1**).

The toxicity of hydrocarbons depends on their viscosity, measured in Saybolt universal seconds (SUS), the cutoff point being SUS = 60. The less the viscosity, the more hazardous it becomes with a higher risk of aspiration. Low surface tension and high volatility are associated factors for more toxicity of hydrocarbons including the chemical activity of the hydrogen side chain (**Table 2**).

High volatility causes hypoxia and direct irritation to the lungs. Toxicity can thus occur by either ingestion or inhalation and less by direct contact to the skin. Petroleum distillates are ingested more while halogenated hydrocarbons are mostly inhaled; even direct exposure to skin can occur. Ingestion can be deliberate or accidental and inhalation happens mostly as an abusing agent and sometimes accidental. Inhalation abuse happens by either sniffing, huffing, or bagging. Sniffing is by inhalation from a container directly or by putting the substance in a container. Huffing is by putting the liquid in a cloth or cloth-like substance and then inhaling it while bagging is putting the volatile hydrocarbons in a bag (plastic or paper) and then breathing and rebreathing through it.

PATHOPHYSIOLOGY

A combustible hydrocarbon such as *Kerosene* is found abundantly in the household and in the community and is one of the frequent causes of poisoning, both as accidental and as suicidal poison. The main effects of these poisons are

TABLE 1: Classification of hydrocarbon with its uses.

Hydrocarbon group	*Example*	*State at room temperature*	*Uses*
Aliphatic	Methane, propane, butane, gasoline, kerosene, mineral spirits, mineral oil, mineral seal oil, diesel oil, n-hexane, naphtha	Gas and liquid	Fuels, liquid fuels, solvents, furniture polish, degreasers, multiple uses in the chemical industry
Aromatic	Toluene, xylene, benzene	Liquids	Used in plastics, pharmaceutical, rubber, chemical, and solvent industries, degreasers
Halogenated	Methylene chloride, chloroform, carbon tetrachloride, trichloroethylene, Freon, methyl bromide, lindane,	Liquids	Solvents cleaning fluids, degreasers, fire extinguishers, paint strippers, fumigants
Others	Turpentine, pine oil, oil of wintergreen, pennyroyal	Liquids	Solvents, household disinfectants, incense

TABLE 2: Properties of hydrocarbons and their effect.

Properties of hydrocarbons	*Inference from the term*	*Effects*
Viscosity	The property to oppose the flow or the liquidity of a substance	Less viscosity, more free flow, and more chances of aspiration
Volatility	The property of liquids to get converted to gas	Causes direct effect on the lungs and causes hypoxia by displacing O_2
Surface tension	Property of the liquid to adhere to a surface	Low surface tension, more chances of aspiration
Lipophilicity	The ability of a substance to attach to the lipid molecule	Crosses the blood–brain barrier and is stored in tissues for long

on the gastrointestinal (GI) tract and then on the lungs due to aspiration. The aspiration is mostly due to the vomiting but can be without vomiting as well, attributable to its low viscosity. Other alkanes such as turpentine oil having high viscosity and low volatility and have less chances for aspiration but are readily absorbed through the GI tract and lungs (on inhalation), and they have toxic effects on the GI tract and the central nervous system (CNS). They are usually excreted by the kidneys after metabolization. Ingestion has a variable absorption rate; the higher the molecular weight, the lesser the absorption.

Alkanes, such as methane, ethane, propane, butane, and pentane, are in the form of gases and when inhaled have local toxic effects on lungs. The effect on the lungs is manifested by injury to the basement membrane between the alveoli and the capillary bed leading to hypoxia and pneumonitis. After absorption, high concentrations are detected in adipose tissues, liver, and other organs such as kidney, brain, lung, heart, thymus, or testes as well. These gases have narcotic properties and can cause hypotension and respiratory arrest as well. The inhaled hydrocarbon gets into the adipose tissues and liver and is stored there for a long time even after the exposure stops. Polycyclic aromatic hydrocarbons (PAH) induce liver enzymes CYP450, CYP1A1 and CYP1A2, CYP1B1, CYP2B, CYP2C, and CYP3A. These enzymes are responsible for the metabolism of hydrocarbons (PAH) in the body. Hydrocarbons after absorption from the lungs by diffusion through the alveoli reach the capillaries and cross the blood–brain barrier due to their lipophilic nature and have high concentration in the brain affecting the gamma aminobutyric acid (GABA), dopamine, and opioid receptors.

After ingestion of PAH, the intestinal CYP450 induced along with other cytochrome enzymes mentioned are responsible for the metabolism. Hydrocarbons cause destruction to stratum corneum and duration of contact, denuded skin, and multiple exposure increase skin absorption. Few hydrocarbons, such as carbon tetrachloride and methylene chloride, get metabolized to toxic substances inside the body leading to involvement and failure of organs, especially the liver.

CLINICAL PRESENTATION

The symptoms of hydrocarbon poisoning are attributed to its main effects on the lungs, GI tract, and brain. Ingestion of hydrocarbon in its liquid form can lead to cough, vomiting, choking sensation, and burning sensation in the stomach. Ingestion in children causes cyanosis and can lead to respiratory difficulty. The respiratory difficulty in children and adults is mostly due to the aspiration which occurs during the episodes of vomiting. Less viscosity, along with low surface tension of substances such as kerosene and gasoline, has more propensities for aspiration from the upper GI tract to the trachea causing hypoxia and pneumonitis. Aspirated hydrocarbon causes the loss of surfactant in the alveolar lining leading to collapse of the affected alveoli and ventilation–perfusion (V/Q) mismatch.

The signs and symptoms of aspiration would start as early as half an hour after ingestion and peaks in about 2 days with coughing and signs of respiratory distress (tachypnea, dyspnea, choking sensation, grunting, labored breathing, hypoxic, and cyanosis). The symptoms vary from mild to severe and on examination can have rales and rhonchi. A patient can develop alveolitis, pulmonary edema, pulmonary infiltrates, collapse of lung, pneumothorax, pneumomediastinum, pneumopericardium, hemoptysis, and fever as well. Upper airway involvement causes irritation, hyperemia, and inflammation.

Organs such as brain get involved though systemic absorption or due to inhalation and further diffusion which is manifested by the depressant effect on the brain as manifested by decreased sensorium, lethargy, and convulsions. It causes demyelination, loss of axons, and deposit of iron in the brain. Hydrocarbons toxicity can cause fatal arrhythmias, sudden cardiac death (sniffing effect), myocardial dysfunction, and intravascular hemolysis. It can cause damage to the kidneys causing acute glomerulonephritis, chronic interstitial nephritis, and renal tubular acidosis. Dermatitis of the exposed skin, deranged hepatic enzymes, and fatty infiltration of liver are a few of the other systemic manifestations encountered. Acute liver failure can occur with halogenated hydrocarbons (carbon tetrachloride and methylene chloride) where the degraded toxic metabolite results in hepatic necrosis. These chlorinated hydrocarbons, such as carbon tetrachloride and methylene chloride, are also found to be carcinogenic.

Sudden sniffing death syndrome is a known entity of hydrocarbon inhalation mostly due to halogenated hydrocarbon but may occur with other hydrocarbon inhalation as well. Sudden onset of tachyarrhythmias occurring as a reactive response to endogenous catecholamine leads to this syndrome.

Specific aromatic hydrocarbons such as benzene can cause aplastic anemia, acute myelogenous leukemia, myelodysplastic syndrome, and lymphomas.

Chronic inhalation of hydrocarbons causes permanent cerebral changes in the form of cerebellar degeneration, dementia, chronic encephalopathy, neuropathy, memory, and attention deficits due to loss of neurons, axonal degeneration, and gliosis.

RED FLAGS

- Shortness of breath following hydrocarbon ingestion/inhalation suggests aspiration.
- Swelling and inflammation of the mouth and oropharynx warrants early airway intervention.
- Sudden onset of arrhythmias and cardiac arrest can occur with hydrocarbon sniffing.
- Halogenated hydrocarbons' ingestion can lead to fulminant hepatic failure.
- Acute kidney injury can occur with hydrocarbon toxicity which may require dialysis.

EVALUATION

History

A history suggestive of consumption of a hydrocarbon, preferably with the details, should be sought. Sudden onset of vomiting in children or adults with a characteristic smell could clinch the cause of the condition. The smell of kerosene, turpentine oil, and sweet gasoline-like odor of benzene would give a clue to the consumption. An occupational history is important as exposure can occur in the workplace. The details about the route of exposure, quantity consumed, time at which exposure occurred, time of onset of symptoms, and nature of symptoms need to be documented. There is a need to identify hydrocarbon with other additives and toxicity (**Table 3**).

The symptoms soon after ingestion, along with symptoms on arrival, should be assessed. The quantity of the hydrocarbon consumed and the time at which the person seeks medical care are important. In chronic abusers, typical skin changes occurring, especially bagging in and around mouth and nose which can be identified.

Evaluation of airway (A), breathing (B), and circulation (C) should be undertaken along with checking the sugar. An arterial blood gas (ABG) analysis could give a clue to the metabolic status of the patient. An X-ray should be done to look out for signs of aspiration. An ECG could suggest any ongoing arrhythmia. An evaluation of the patient should focus on the GI tract and lung involvement along with the involvement of the brain. Evaluation of the other organs should be done if the history and examination, along with the identified poison, can cause particular organ damage.

Physical Examination

Examination findings may reveal presence of facial swelling, ulceration, and other skin changes. Look at the tongue and oral cavity for swelling, redness, ulceration, and any signs of burns. A thorough general examination (pallor, cyanosis, clubbing, icterus, pedal edema) and a head-to-toe examination along with systemic examination of respiratory system(mainly focuses on signs of pneumothorax and mediastinal shift). Evaluation of cardiac status would require a look for signs of failure, arrhythmias assessed by tachycardia with or without pulse, pedal edema, and right hypochondriac tenderness. Pain over the epigastric region could occur due to the ingestion causing local gastric irritation, ulceration, and hematemesis. A neurological assessment needs to be done to find out the level of consciousness of an individual along with any signs of seizures. Renal involvement could be assessed by the patient's acidotic status along with decreased urine output, swelling involving the periorbital region, lower limb, or generalized edema.

TABLE 3: Hydrocarbons with additives and systemic toxicity.

Hydrocarbon	*Toxicity*
Camphor	Neurotoxicity and convulsions
Halogenated hydrocarbon	Arrhythmias and liver failure
Aromatic hydrocarbon	Bone marrow depression and leukemia
Metals	Neurotoxicity
Pesticides	Convulsions, cholinergic crises, and respiratory depression

Interpretation of the Findings

History suggestive of accidental consumption of hydrocarbons or chronic abuse coupled with the smell of hydrocarbon helps to find out the signs and symptoms that are consistent with the poisoning, and a physical examination helps to arrive at a diagnosis of hydrocarbon ingestion or inhalation. Certain symptoms can occur due to concomitant toxicity with other substances apart from hydrocarbon toxicity. CNS depressants effect can be due to the use of sedatives or alcohol consumption; similarly, pneumonitis may be due to other poisons such as organophosphorus and paraquat. Pain over the right upper quadrant could also be due to acute fulminant hepatitis along with an enlarged liver. Fever and leukocytosis are common and may not reflect infection.

INVESTIGATION

The diagnosis of hydrocarbon poisoning could be done with the history, characteristic smell, symptoms, and signs consistent with the history. Few investigations could directly give a clue to the offending hydrocarbon poisoning—urine for hippuric acid and toluene, urine for phenol and S-phenylmercapturic acid (S-PMA) for benzene, and carbon monoxide levels for methylene chloride. Certain investigations which should be carried out would be complete blood count (CBC), renal profile, and liver function test. ABG analysis should be done which would help to determine the involvement of various organs due to poisoning and to find out any other associated poisoning. An X-ray of chest is done to check for signs of aspiration (**Fig. 1**), such as pneumatocele, pleural effusion, pneumothorax, and pneumonia. For coexisting infections, sputum cultures may be of help to rule out other bacterial pneumonia.

For chronic abusers (inhalant hydrocarbons), MRI could help to see the involvement of the brain in the form of atrophic changes and hypointensity in T2-weighted images involving the thalamus and basal ganglia.

TREATMENT

Management of a patient of suspected hydrocarbon poisoning would depend upon the ingested or inhaled poison with associated organ involvement and radiological finding encountered. There is no specific antidote available for hydrocarbon poisoning. The patient should be taken to the bed and connected to the monitor; start oxygen if the SpO_2 is <94% and get IV line secured. Begin with an assessment of

FIG. 1: Aspiration pneumonia due to kerosene.

Courtesy: Department of Emergency, Apollo Hospitals, Bilaspur, Chhattisgarh, India.

the airway and the need for airway management including the placement of advanced airway. Any oral or oropharyngeal swelling and hoarseness of voice would warrant an early definitive airway. Assessment of breathing should include the rate, effort, respiratory distress, development of cyanosis, low SpO_2, noisy breathing, audible wheezes and finding consistent with pneumothorax, and consolidation. This would require oxygenation, ventilation, nebulization with beta-agonists, intercostal drain (ICD) placement for pneumothorax and prevention of secondary infection with the use of appropriate antibiotics.

Poisoning due to ingestion of hydrocarbons with no symptoms should not be lavaged and activated charcoal use should be avoided as this could increase the risk of aspiration and pneumonitis. In case of hydrocarbons with inherent toxicity [CHAMP (*C*amphor, *H*alogenated hydrocarbons, *A*romatic hydrocarbons, *M*etals, *P*esticides)] or mixed with other substances, gastric lavage may be undertaken by securing the airway by endotracheal intubation. Activated charcoal may be used in such cases if the substance gets adsorbed. A thorough decontamination should be undertaken (removing all the clothes and giving a full bath to remove the skin contaminants).

Patients who are symptomatic and have X-ray changes suggestive of aspiration should be hospitalized. Early use of surfactant in aspiration could help in improving the oxygenation and prevent the development of pneumonitis in cases where the oxygen index is high; PaO_2/FiO_2 ratios are low with low lung compliance. Use of corticosteroids is not of much benefit in cases of hydrocarbon pneumonitis.

Management of pneumonitis, along with respiratory distress, would require mechanical ventilation. There occurs a large V/Q mismatch leading to the use of high positive end-expiratory pressure (PEEP) for ventilating these cases. Risk for barotraumas due to high PEEP can be managed with high-frequency jet ventilation (HFJV) and extracorporeal membrane oxygenation (ECMO), this being the last resort if all methods fail though it carries a poor outcome.

Cardiac arrhythmias occurring due to hydrocarbon poisoning could be managed using advanced cardiac life support (ACLS) or pediatric advanced life support (PALS) protocols. Avoid using catecholamine as it can cause worsening of arrhythmias [use short-acting beta-blockers (esmolol, metoprolol) for cardiac dysrhythmias]. Epinephrine can cause arrhythmias in acute poisoning and should be avoided (use vasopressin).

N-acetylcysteine (NAC) for fulminant hepatic failure due to carbon tetrachloride and hyperbaric oxygen therapy for methylene chloride or carbon tetrachloride poisoning can be used.

Skin involvement may present as burn which needs to be washed with warm water, decontaminated and managed as per the standard burn protocol. Skin rash occurring due to chronic exposure, over the mouth and nose, needs to be kept clean, prevented from secondary infection, and re-exposure needs to be stopped.

Supportive care, prevention of organ failure, and treating secondary infection remain the mainstay of treatment. Management of hydrocarbons toxicity is summarized in **Flowchart 1**.

DISPOSITION

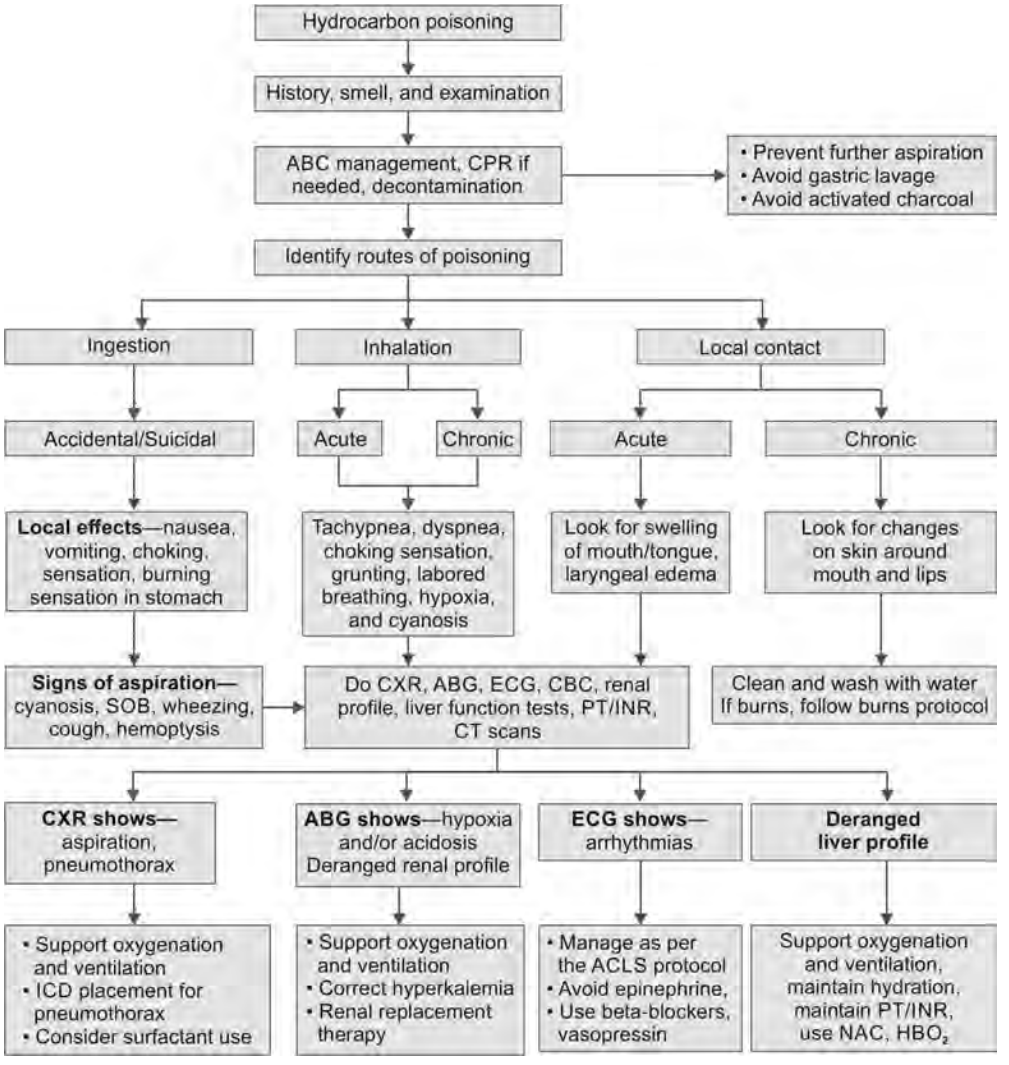
Patients needing ventilation support, high FiO_2 and PEEP, use of vasopressors for maintaining blood pressure, altered sensorium, and multiorgan involvement should be managed in intensive care unit (ICU), and those with minimal symptoms of respiratory involvement, i.e., conscious patients, can be managed in wards.

Patients with hydrocarbon ingestion/inhalation with almost no symptoms along with no respiratory or CNS involvement should be in observation for 6 hours followed by X-ray. If the patient remains stable and symptom-free, then he/she can be discharged home. In case symptom appears, the patient would need hospitalization.

SUMMARY

Hydrocarbons are organic compounds of carbon and hydrogen occurring in liquid and gaseous states.

- Toxic effects of hydrocarbons are attributed to their viscosity, volatility, surface tension, and hydrogen side chain.
- Hydrocarbon toxicity occurs due to aspiration, inhalation, and by dermal contact.
- Aspiration pneumonitis, cardiac arrhythmias, seizures, hepatic failure, renal failure, and bone marrow depression are complications of various hydrocarbons.
- Sniffing death syndrome is a dreaded complication of hydrocarbon inhalation abuse.
- There is no antidote for hydrocarbon poisoning as of date.
- Symptomatic care along with close observation and monitoring, organ support, and preventing secondary infection are the cornerstones of management.
- Giving gastric lavage and use of activated charcoal are contraindicated except in selective cases.
- Patients with aspiration would require ICU care with supplemented oxygenation and ventilation though the symptoms of aspiration can be delayed.
- Cardiac arrhythmias need to be managed as per ACLS guidelines with a caution to avoid use of catecholamines.
- Patients of hydrocarbon aspiration/inhalation can be discharged after 6 hours if they remain symptom-free and chest X-ray is normal.



Hydrocarbon poisoning
History, smell, and examination
ABC management, CPR if needed, decontamination
• Prevent further aspiration
• Avoid gastric lavage
• Avoid activated charcoal
Identify routes of poisoning
Ingestion
Inhalation
Local contact
Accidental/Suicidal
Acute
Chronic
Acute
Chronic
Local effects—nausea, vomiting, choking, sensation, burning sensation in stomach
Tachypnea, dyspnea, choking sensation, grunting, labored breathing, hypoxia, and cyanosis
Look for swelling of mouth/tongue, laryngeal edema
Look for changes on skin around mouth and lips
Signs of aspiration—cyanosis, SOB, wheezing, cough, hemoptysis
Do CXR, ABG, ECG, CBC, renal profile, liver function tests, PT/INR, CT scans
Clean and wash with water If burns, follow burns protocol
CXR shows—aspiration, pneumothorax
ABG shows—hypoxia and/or acidosis Deranged renal profile
ECG shows—arrhythmias
Deranged liver profile
• Support oxygenation and ventilation
• ICD placement for pneumothorax
• Consider surfactant use
• Support oxygenation and ventilation
• Correct hyperkalemia
• Renal replacement therapy
• Manage as per the ACLS protocol
• Avoid epinephrine,
• Use beta-blockers, vasopressin
Support oxygenation and ventilation, maintain hydration, maintain PT/INR, use NAC, HBO2

(ABC: airway, breathing, circulation; ABG: arterial blood gas; ACLS: advanced cardiac life support; CBC: complete blood count; CPR: cardiopulmonary resuscitation; CT: computed tomography; CXR: chest X-ray; ECG: electrocardiogram; HBO_2: hyperbaric oxygen; ICD: Intercostal drain; INR: international normalized ratio; NAC: N-acetylcysteine; PT: prothrombin time; SOB: shortness of breath)

211
CHAPTER

Caustic Ingestion

Narendra Nath Jena, Subbulakshmi Dhanabal

INTRODUCTION

Caustic ingestion is a grave public health problem. It is more common in the developing countries, but still seen in developed countries. It is a medical emergency and shows diverse clinical presentations. The ingestion of caustic substances has devastating effects on the upper gastrointestinal (GI) and respiratory tracts and the caustic injury is associated with numerous life-threatening complications. Caustics, also known as corrosive, are chemical and known to cause injury when they come in contact with tissue. Strong acids, with pH < 3 and strong alkali with pH > 11, are more dangerous to human exposure. Caustics are used both in household and in industrial products as hydrochloric/sulfuric acid, sodium/potassium hydroxide, and others. Eyes, face, and extremities are most affected while they can cause mortality if ingested. On exposure to caustic, immediate water irrigation is done followed by pain management, fluid, and electrolyte therapy. Special attention is required for GI exposure of caustic as this is associated with a high rate of morbidity and mortality.

PATHOPHYSIOLOGY

The degree of tissue injury is determined by several factors (**Fig. 1**): pH, concentration, duration of contact, volume, and titratable acid or alkaline reserve. Significant injuries are caused with acid at a pH < 3 and alkalis at a pH > 11. Litmus paper can be used to determine the pH in the emergency department. Solid or granular caustics often injure the oropharynx and proximal esophagus, whereas liquid alkali ingestions are characterized by more extensive esophageal and gastric injuries. Esophageal mucosal burns from caustic ingestions are classified by a visual endoscopic grading system, which correlates with the risk of future complications. Following the initial mucosal injury, tissue remodeling occurs over roughly 2 months. In mild cases, normal esophageal function is restored, but in severe cases, dense scar tissue forms, resulting in stricture formation. Esophageal strictures are a source of significant morbidity and may require long-term treatments with dilations, stenting, or surgery. Early phases of remodeling, particularly 2–14 days after exposure, are associated with increased tissue friability and a higher risk of perforation, both spontaneous and iatrogenic. *Alkali injury*: Alkali injuries induce a deep tissue injury called *liquefaction necrosis.* This process includes protein dissolution, collagen destruction, fat saponification, cell membrane emulsification, submucosal vascular thrombosis, and cell death.

Acid injury: Acid ingestion causes *coagulation necrosis*. In this process, hydration (H^+) ions desiccate epithelial cells producing an eschar. This process leads to edema, erythema, mucosal sloughing, ulceration, and necrosis of tissues. Both acids and alkalis cause fibrosis and stricture formation.

Esophageal injury mechanism by caustic ingestion (**Table 1**) is different and complex; it initially starts with lipid peroxidation and in later stage, stricture formation develops. A high concentration of malondialdehyde is found 24 hours postexposure, which is the end product of lipid peroxidation and glutathione. A high concentration of malondialdehyde also indicates the presence of reactive oxygen species and endogenous free radicals' scavengers in the esophageal tissues exposed to sodium hydroxide. Also, low glutathione in tissues exposed confirm the presence of reactive oxygen species and damage of free radicals.

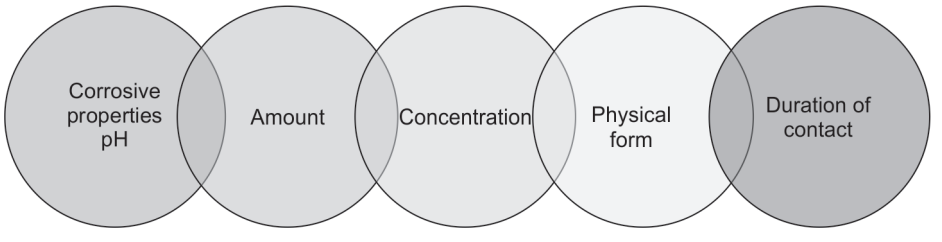

FIG. 1: Factors affecting the injury by caustic.

ETIOLOGY

Many chemicals used in industry have caustic potential. Household caustics are often less concentrated forms of industrial-strength cleansers (**Table 2**).

TABLE 1: Pathophysiology of esophageal injury.

Within minutes of caustic ingestion	Esophageal injury begins within minutes—eosinophilic necrosis swelling and hemorrhagic congestion
4–7 days of caustic ingestions	During this period, inflammation, mucosal sloughing, bacterial invasion, and appearance of granulation occur. Ulcer gets covered by the fibrinous layer and perforation may occur if it penetrates the mucosal plane
4th day of caustic ingestion	Fibroblast at the injury site
5th day of caustic ingestion	Esophageal mold consists of dead cells and secretion
10th day of caustic ingestion	Esophageal repair begins
1st month from caustic ingestion	Esophageal ulcer begins to epithelialize

TABLE 2: Caustic compounds.

Alkalis: Caustic compounds	*Acids: Caustic compounds*
Properties: pH > 7, tasteless, odorless, causes liquefaction necrosis, esophageal injuries are common while duodenal injuries are less common	*Properties:* pH < 7, pungent odor and noxious taste, coagulation necrosis, less esophageal injuries, more gastric injury
Sodium hydroxide (industrial chemicals, drain openers, oven cleaners)	*Sulfuric acid* (automobile batteries, drain openers, explosives, fertilizers)
Potassium hydroxide (drain openers, batteries)	*Acetic acid* (printing and photography, disinfectants, hair perm neutralizer, pickling solution)
Calcium hydroxide (cement, hair relaxers, perm products)	*Hydrochloric acid* (cleaning agents, metal cleaning, chemical production, swimming pool products)
Ammonium hydroxide (hair relaxers and perm products, dermal peeling/exfoliation, toilet bowl cleaners, glass cleaners, fertilizers)	*Hydrofluoric acid* (rust remover, petroleum industry, glass and microchip etching, jewelry cleaners)
Lithium hydroxide (photographic developer, batteries)	*Formic acid* (model glue, leather and textile manufacturing, tissue preservation)
Sodium tripolyphosphate (detergents)	*Chromic acid* (metal plating, photography)
Sodium hypochlorite (bleach)	*Nitric acid* (fertilizer, engraving, electroplating)
	Phosphoric acid (rust proofing, metal cleaners, disinfectants)

CLINICAL FEATURES

Clinical presentation varies and depends on the type/quantity of the agent ingested, timing of ingestion, and presence of food in the stomach. Burns to the lips, mouth, and oropharynx may be seen, but this does not necessarily correlate with the degree of the injury to the esophagus or stomach. The initial symptoms of caustic ingestion include drooling and dysphagia. In severe cases, pain, vomiting, and sometimes bleeding develop immediately in the mouth, throat, chest, or abdomen. Airway burns may cause coughing, tachypnea, or stridor (**Table 3**). Swollen, erythematous tissue may be visible intraorally; however, caustic liquids may cause no intraoral burns despite serious injury farther down the GI tract. The presence or absence of oropharyngeal burns in children does not predict the presence of esophageal or gastric burns. Esophageal perforation may result in mediastinitis, with severe chest pain, tachycardia, fever, tachypnea, and shock. Gastric perforation may result in peritonitis. Esophageal or gastric perforation may occur within hours, after weeks, or any time in between. Esophageal strictures can develop over weeks, even if initial symptoms had been mild and treatment had been adequate.

EVALUATION

History: The key priority is rapid airway assessment and stabilization. Following that, obtain a directed history to determine the type, amount, and timing of the ingested caustic and the presence of co-ingestants. Determine if the ingestion was intentional or unintentional. *Physical examination:* Look for signs of respiratory distress or circulatory shock. With ingestions, look for signs of oropharyngeal injury (mucosal burns, drooling), respiratory injury (dysphonia, coughing, stridor, wheezing), and gastric injury (vomiting, epigastric tenderness). Streaks of caustic burns on the face or chest are called "dribble burns."

Assess for hemodynamic instability. Causes of shock include GI bleeding, complications of GI perforation, volume depletion, and toxicity from co-ingestants. Examine for peritoneal signs due to hollow viscous perforation. Consider mediastinitis in patients complaining of chest discomfort, and palpate the chest wall and neck for signs of subcutaneous emphysema. Inspect the eyes for ocular burns and the skin for splash and dribble burns.

TABLE 3: Clinical presentation.

Gastrointestinal tract	Drooling; dysphagia; odynophagia; severe pain of lips, mouth, throat, chest, abdomen; vomiting; hematemesis
Respiratory tract	Hoarseness, stridor, epiglottitis, laryngeal edema and ulceration, pneumonitis, impaired gas exchange
Eye	Pain, irritation, clouding of cornea, decreased vision
Skin	Dribble marks on the face, chest, and legs; first, second, or third-degree burns

INVESTIGATIONS

Intentional ingestions are associated with higher grades of GI tract injury, with or without clinically obvious signs. Laboratory evaluation should include a venous or arterial blood gas, electrolyte panel, hepatic profile, complete blood count, lactate, and blood type and screen. Strong acid ingestions may be associated with both severe anion gap (e.g., sulfuric acid) and nongap acidoses (e.g., hydrochloric acid). In suicidal patients, obtain acetaminophen and salicylate levels to screen for potential co-ingestants. An ECG is indicated following a hydrofluoric acid exposure to check for QT interval prolongation from hypocalcemia. Esophagogastroduodenoscopy should be performed in the first 12–24 hours postingestion, with great care to avoid iatrogenic perforation. The grade and extent of the lesions (**Table 4**) of the upper GI tract can be determined and classified according to Zargar's modified endoscopic classification of burns due to caustic ingestion. Severe hypopharyngeal burns are an absolute contraindication for esophagogastroduodenoscopy.

MANAGEMENT

Initial Management

If only a small amount is ingested, observe and discharge the patient from the ED if accepting liquid or semi-solid food orally, asymptomatic, and oral examination is normal. In major ingestion, pay special attention to the airway/oxygenation. Keep the patient nil per oral. Intravenous fluids and nutritional support should be started. Proton-pump inhibitors (reduce exposure of the injured esophagus to gastric acid, which may result in decreased stricture formation), antibiotics (if there is evidence of perforation), and pain relief medication should be added. Emergency surgical intervention is indicated in case of perforation or peritonitis or if uncontrolled massive hematemesis occurs.

Activated charcoal is *relatively contraindicated* in caustic ingestions because of poor adsorption and endoscopic interference. Other measures which should not be included in initial management are emesis, nasogastric tube insertion, and lavage. Do not induce emesis as this increases the risk of mucosal injury and perforation. Do not try to insert nasogastric tube/take lavage as this may cause esophageal perforation and increase the risk of aspiration. Do not try to neutralize the substance (risk of heat production resulting from this exothermic reaction).

TABLE 4: Endoscopic grading according to Zargar classification for caustic injuries.

Grade	*Description*
Grade 1	Edema and hyperemia of the mucosa
Grade 2A	Superficial localized ulcerations, exudates, whitish membranes, blisters, erosions, hemorrhages, and friability
Grade 2B	Circumferential and deep ulcerations
Grade 3A	Multiple and deep ulcerations and small scattered areas of necrosis
Grade 3B	Extensive necrosis
Grade 4	Perforation

Nutrition

The endoscopic grade of lesions needs to be assessed for planning nutritional support in patients with caustic ingestion. Patients with grade 1/2A lesions on endoscopy can tolerate oral feeds, while those with grade 2B/3A lesions will need nasoenteral feeding. Patients with grade 3B lesions require gastrostomy for enteral feeding and rarely need total parenteral nutrition (TPN).

Acute Presentation

Within 48–72 hours of corrosive ingestion: Upper GI endoscopy should be performed on day 1–2 (ideally between 12 and 24 h of ingestion). If endoscopy reveals only mild lesions, then the patient can be discharged and clinical follow-up should be done at 1 month. If severe lesions are found on endoscopy, then surgical gastrostomy is indicated, which should be followed by repeat endoscopy and dilatation after 3 weeks.

Delayed Admission

Within 72 hours to 3 weeks of corrosive ingestion: No endoscopy is indicated here. Gastrostomy should be done if there is severe dysphagia. Endoscopy and dilatation of stricture (if present) should be done 3 weeks after ingestion.

Late Admission

More than 3 weeks of ingestion requires endoscopy and dilatation of stricture. If the procedure is successful, then a follow-up endoscopy should be done at 1 month. If the procedure is unsuccessful, then surgical gastrostomy is performed, which is followed by retrograde dilatation of stricture after 10 days of operation.

COMPLICATIONS

Aspiration of corrosive substances into the respiratory tree may cause endotracheal or bronchial necrosis with mediastinitis. Acute kidney injury, disseminated intravascular coagulation, acid–base disturbances, and pneumonia may also occur. Esophageal stricture formation is the most feared long-term complication; stenosis gastric antrum or pylorus may also occur and so may fistula formation. Stricture formation begins weeks to months after injury and is the most important consequence of corrosive poisoning. The procedures used for prevention and treatment of strictures are as follows:

- *Dilatation therapy*: This is done 3–6 weeks after injury; progressively larger bougies are passed over endoscopically placed guidewires for dilatation
- *Surgery*: Esophageal strictures resistant to dilatation therapy may require surgery that includes resection of stricture surgically and esophageal bypass surgery.

DISPOSITION AND FOLLOW-UP

Asymptomatic patients, with low-risk ingestions and no signs of drooling, stridor, or vomiting and who tolerate food or drink, may be discharged from the ED after a period of observation. Admit all patients with symptomatic caustic ingestions.

Patients with grade 1 injuries can be discharged from the hospital after endoscopy, provided they can tolerate oral fluids and food. Grade 2A injuries warrant hospitalization to ensure that symptoms and injury do not progress. Grade 2B and 3 injuries are significant, require enteral or parenteral nutrition, and have an early risk for bleeding or perforation; admit these patients to an intensive care unit. Contact the regional poison control center for data collection purposes and assistance with management.

SUMMARY

Caustic substance ingestion associated with great potential for morbidity and mortality. Close monitoring of hemodynamics, maintaining the patient's airway, aggressive supportive care, remains paramount. Currently, literature do not support the use of parenteral corticosteroids or systemic antibiotics without concomitant signs of infection following caustic ingestion. Early consultation with a gastroenterologist, otolaryngologist, or surgeon should be taken, because the patient may require esophagogastroduodenoscopy (EGD) or surgical intervention. Patients exposed to hydrofluoric acid by any route require decontamination as well as specialized treatments, including topical, regional, and systemic treatments to reduce burns, pain, and systemic complications. These patients may also require early consultation with a surgeon or interventional radiologist, should there be a need for surgical debridement or intra-arterial therapies.

212
CHAPTER

Inhaled Toxins

Subramanian Senthilkumaran, Ponniah Thirumalaikolundusubramanian

INTRODUCTION

Inhalation injury is a clinical syndrome that occurs when the respiratory system is exposed to a wide range of chemicals in different forms, namely smoke, gases, vapors, or fumes. Moreover, liquids and solids can also be inhaled in the form of mists, aerosols, or dust. These exposures happen mostly in the setting of industrial chemical accidents and residential fires. Inhaled constituents may directly injure the respiratory system at various levels, leading to a wide range of damage to the airways and/or parenchyma resulting in nasal mucositis, tracheitis, and bronchitis to pulmonary edema. These may also result in systemic toxicity when absorbed. The severity and pathogenesis of inhalational injury depend upon the nature of the chemical and duration of exposure as well as on the quantity and intensity of exposure to the toxin/chemical.

ETIOLOGY

Inhalation injury characteristically results from exposure to harmful substances which can be broadly classified into asphyxiants, irritants, and systemic toxins. Occupational exposures occur due to working in poorly ventilated areas or entering into work without proper personal protective equipment (PPE), and vary significantly based on the exposed chemicals. Common causative factors in residential fires are heat, inert gases, and chemical products of combustion such as carbon monoxide (CO), hydrogen cyanide, sulfur dioxide, and particulate matter. In few cases of acute inhalational injury, more than one substance or mechanism may be involved.

PATHOGENESIS

The pathophysiology of inhalation injury reveals the heterogeneity of inhalation exposures. Major categories of injury include direct thermal injury to the airway, asphyxiation, systemic toxic effects, etc. Inhalation injury may affect the respiratory system at various levels. Anatomically, the injuries are classified into (1) thermal injury limited to upper airway except in the circumstance of steam jet exposure, (2) local chemical irritation throughout the respiratory tract, and (3) systemic toxicity as may occur with inhalation of CO or cyanide.

The location and severity of injury depend on various factors including the characteristics of the toxic agent, the quantity and diameter of the particles in the fumes, the duration of the exposure, the solubility of the gases, environment, and host factors (**Table 1**).

Upper Airway Injury

Thermal damage is usually limited to the oropharyngeal region, due to the efficient heat exchange. Poor conductivity of air and reflex closure of the larynx help to protect the lower lung from direct thermal injury. The immediate injury result in massive edema of the tongue, epiglottis aryepiglottic fold, airway compromise leading to rapid clinical deterioration and these are further worsened over a matter of hours as in cases of combined burn and inhalation injury, which promotes early edema formation in the upper airway.

In addition to the acute insult, damage to ciliary function impairs physiological clearance of the airway, leading to an enhanced risk of bacterial infection for several weeks. Additionally, the increased production of copious secretions causes distal airway obstruction, atelectasis, and impaired gas exchange.

Tracheobronchial Injury

Frequently, the chemicals in smoke cause injury to the tracheobronchial tree with the exception of inhalation of

TABLE 1: Risk factors.

Inhaled toxin-related	*Host factors (individual related)*	*Others*
Concentration	Exertional state of the victim	Ventilation of the room
Quantity	Extremes of age	Environmental status
Duration of exposure	Underlying lung condition(s)	
Particle size	Debilitating illness(s)	
Water solubility	History of smoking	

steam. Nevertheless, toxic inhalation of noxious gases such as chlorine, liquids such as acid or alkali, and smoke from fire is associated with a similar process.

The tracheobronchial region is abundantly innervated by vasomotor and sensory nerve endings. So, neuropeptides are often released because smoke inhalation stimulates these nerves. These neuropeptides induce reflex bronchoconstriction and release nitric oxide synthase to generate reactive oxygen species. These neuropeptides function as tachykinins, inducing an inflammatory response with the downstream effects of bronchoconstriction, increased vascular permeability, and vasodilation. These potentiate local cellular damage and loss of hypoxic pulmonary vasoconstriction, which increases several fold of bronchial blood flow. In addition, the increased bronchial blood flow activates the polymorphonuclear leukocytes and release cytokines to the lung, increasing the host inflammatory response. Moreover, the damage of an intact bronchial epithelium and the effects of nitric oxide synthase result in a loss of plasma proteins and fluid leak from the intravascular space into the alveoli and bronchioles. This transvascular shift of protein results in inflammatory exudate and cast formation within the airways, leading to alveolar collapse. These progressions contribute to ventilation–perfusion mismatch, a major mechanism for hypoxemia following the inhalation injury.

Parenchymal Injury

The cascade of inflammatory mediators following inhalation injury results in the interaction of irritant substances with lung parenchyma, leading to both hyperinflation and atelectasis. The debris from mucosal sloughing, intrapulmonary hemorrhage, inflammatory exudate, and increased transvascular fluid flux results in mechanical obstruction of small airways causing hyperinflation and air trapping. The alveolar collapse occurs due to impaired surfactant production and activity, leading to segmental atelectasis and, therefore, impaired oxygenation. Besides, a severe imbalance in alveolar hemostasis and decreased fibrinolytic activity, with massive fibrin deposition in the airways, causes decreased lung compliance, loss of hypoxic pulmonary vasoconstriction, increased ventilation–perfusion mismatch, and increase in dead space ventilation. The risk factors that determine/influence inhalation injury are given in **Table 1**.

CLINICAL FEATURES

The clinical symptoms due to highly soluble substances cause persistent coughing and severe burning in the eyes, nose, throat, and large airways within minutes of exposure, which result in lacrimation, rhinitis, epistaxis, and pharyngitis as well as retching and shortness of breath with wheezing. Physical findings including facial injury, singed nasal hairs, soot in the proximal airways, carbonaceous sputum production, hoarseness of voice, and stridor which indicate the diagnosis of upper airway injury.

Signs of lower respiratory tract injury may include tachypnea, decreased breath sounds, rales, rhonchi, or use of accessory respiratory muscles. Respiratory failure may occur with 12–48 hours after smoke exposure. A faster time is associated with more severe injury. CO poisoning should be assumed in any patient who presents after smoke inhalation until excluded by a normal carboxyhemoglobin level as measured by CO-oximetry. Generalized symptoms such as headache, giddiness, nausea, or vomiting may develop in few cases.

INVESTIGATION

Complete blood count, electrolytes, blood urea nitrogen, creatinine, lactate level, and toxicology screen are required. An arterial blood gas analysis with CO-oximetric measurement for oxyhemoglobin, carboxyhemoglobin, methemoglobin, and cyanide levels, as indicated, has to be carried out. Chest radiography is done as a part of the initial evaluation, although it may have a low sensitivity for inhalation injury. The presence of lung opacities on initial chest films has been implicated as a marker of severe injury with a poor prognosis. A CT scan of the thorax may reveal ground-glass opacities in peribronchial distribution, within few hours of inhalation injury.

DIAGNOSIS

The diagnosis of inhalation injury may be assumed based upon clinical findings in the setting of smoke exposure, but a definitive diagnosis relies upon direct examination of the airways. The fiberoptic bronchoscopy allows assessing the patency of the airway. Clinical signs of inhalation injury include mucosal erythema and edema, blistering, ulceration, bronchorrhea, fibrin casts, or evidence of charring. Bronchoscopic criteria, used to grade inhalation injury, are depicted in **Table 2**. The grading and findings correlate well with mortality as well as gas exchange.

MANAGEMENT

Prehospital Care

- Immediate evacuation of a victim from the site of fire/toxin to limit the time of exposure.

TABLE 2: Bronchoscopy criteria used to grade inhalation injury and findings.

Grading scale	*Bronchoscopy findings*
0 (no injury)	Absence of carbonaceous deposits, erythema, edema, bronchorrhea, or obstruction
1 (mild injury)	Minor or patchy areas of erythema or carbonaceous deposits in the proximal or distal bronchi
2 (moderate injury)	A moderate degree of erythema, carbonaceous deposits, bronchorrhea, or bronchial obstruction
3 (severe injury)	Severe inflammation with friability, copious carbonaceous deposits, bronchorrhea, or obstruction
4 (massive injury)	Evidence of mucosal sloughing, necrosis, and endoluminal obliteration

- Removal of all clothing and jewelry as soon as possible as they may be contaminated by toxins [(such as hydrogen cyanide (HCN)] or may retain heat.
- Decontamination is done using full isolation precautions.
- *Clinical assessment*:
  - Expeditious assessment of the patient's airway, breathing, and circulation.
  - Assess for any life-threatening injuries which may take precedence.
  - Bedside assessment of chest for adequacy of breathing in a nonintubated patient by respiratory rate, chest wall motion, and auscultation of air movement, and all these shall be frequently re-evaluated.
- Administration of humidified high-flow oxygen to maintain oxygen saturation >90%.

Airway

- Securing the airway is pivotal in patients with inhalation injury.
- It is better to intubate early when swelling is least and the patient is still physiologically intact.
- The criteria for early intubation are based on the clinical signs such as deep burns to the face or neck, blisters or edema of the oropharynx, stridor, use of accessory muscles, respiratory distress, sub- and suprasternal retractions, or hypoventilation.
- Intubation in victims with inhalation injury is potentially difficult and has its own risk, and hence prefers to use awake fiberoptic intubation in order to preserve the respiratory drive and spontaneous ventilation.
- Usage of video laryngoscope for intubation is an emerging and promising technique.
- Mask ventilation is an alternative in situations where one "can't ventilate or can't intubate," as in nonburn patients with injury in supraglottic airways or in those with difficulties for cricothyrotomy and tracheostomy
- Although early tracheostomy provides comfort and security to patients, there are no significant differences in the length of stay, incidence of pneumonia, survival, or duration of ventilator use, when compared with late tracheostomy.
- In case of anterior neck burns, tracheostomy shall be delayed until 5–7 days after skin grafting.

Fluid Resuscitation

- The goal of fluid resuscitation is to maintain an adequate urine output.
- The fluid requirements are not predicted by the depth and size of their burns.
- The formula of fluid resuscitation should be used only as a guide and titrated to clinical endpoints.
- Ringer lactate is the fluid of choice.
- Due to an increase in insensible loss of fluid through the injured lung in victims of smoke inhalation injury, these cases require 25% higher fluid requirement.
- As aggressive resuscitation may increase pulmonary microvascular hydrostatic pressure and result in edema formation. Hence, there is a need for close monitoring of fluid balance in order to ensure adequate resuscitation and avoidance of complications.

Nutrition

- Patients with inhalation injury may also demonstrate marked hypermetabolism.
- Enteral nutrition formulas with a low respiratory quotient will help to limit carbon dioxide production, improving the patient's ability to keep up with respiratory demands.

Pulmonary Care

- It is aimed to relieve bronchospasm and reduce pulmonary secretions by pulmonary toileting so as to prevent the airway obstruction and atelectasis leading to pneumonia.
- Aerosolized bronchodilators are administered to relax the bronchial muscle, stimulate mucociliary clearance, decrease airflow resistance, and improve dynamic compliance.
- Nebulization of levosalbutamol to relieve bronchospasm and racemic epinephrine for stridor
- Tiotropium, a muscarinic receptor antagonist, is administered at 4–6 hours' interval to improve PaO_2/FiO_2 ratio as well as decrease the peak airway pressure after smoke inhalation injury.
- A combination of aerosolized mucolytic agents, such as N-acetylcysteine alternating with aerosolized heparin, is done for the airway clearance along with therapeutic coughing, chest physiotherapy, deep breathing exercise, and postural drainage.
- Prophylactic antibiotics and corticosteroids are not indicated following smoke inhalation.

Mechanical Ventilation

- The goal of mechanical ventilation in smoke inhalation injury is to keep the alveoli patent, oxygenate the lungs, and prevent barotrauma.
- The optimal ventilator strategy for patients with burns and inhalation injury is not well defined.
- Increased production of carbon dioxide requires high minute ventilation to maintain a normal pCO_2 and may require ventilatory support to achieve.
- The lungs are ventilated using a tidal volume of 6–8 mL/kg with a respiratory rate of 16–18 breaths/min and peak airway pressure <35 mm Hg should be maintained.
- FiO_2 is adjusted to maintain PaO_2 between 80 and 100 mm Hg.
- Optimal positive end-expiratory pressure (PEEP) is administered to maintain the desired airway pressure below which the alveoli collapse.
- Even simple prone positioning has also been found to improve oxygenation.
- The newer modes of ventilation such as high-frequency percussive ventilation, high-frequency oscillatory ventilation, pressure control inverse ratio ventilation, and airway pressure release ventilation have proven to be beneficial in managing patients with smoke inhalation injury.

Future Therapies

- The use of extracorporeal membrane oxygenation (ECMO) is beneficial for the victims who develop severe respiratory failure after smoke inhalation injury.

- Newer agents, such as perfluorohexane and porcine pulmonary surfactant, are being investigated for their beneficial role in attenuating the release of inflammatory mediators in the airway and lungs.

Special Population

- In pediatric patients, airway compromise is the most common cause of severe morbidity and mortality, likely due to the small size of the airway. The threshold for intubation needs to be lower in pediatric patients due to the potential for rapid development of airway edema.
- In older adults, mortality from burns increases to 6-fold due to lower physiological reserves, decrease in lung mechanics, reduction in lean body mass, and comorbidities. Additionally, elderly burn patients are more likely to develop complications such as pneumonia and urinary tract infections while on treatment.
- Patients with inhalation injury due to agents other than smoke are typically managed in the same fashion as for smoke inhalation, with an exception of monitoring for CO poisoning.

ASPHYXIANTS

Asphyxiants are gases that deprive body tissues of oxygen and it may be gases, liquids, or solids, or their metabolites. They are broadly classified into two categories: (1) Simple, and (2) Systemic. Simple asphyxiants such as carbon dioxide, nitrogen, and propane, when present in high concentrations in air, especially within a confined space, merely displace oxygen from ambient air and reduce fraction of inspired oxygen and subsequent hypoxemia whereas systemic asphyxiants such as CO, cyanide, and hydrogen sulfide interfere with oxygen transport system or with mitochondrial oxidative phosphorylation and thereby cause tissue hypoxia. However, any gas in high concentration can act as an asphyxiant. Even though methane, ethane, argon, and helium are more innocent at low concentrations, at high levels they can displace oxygen or block the reaction of cytochrome oxidase or hemoglobin, impairing cellular respiration and oxygen transport.

Mild symptoms of asphyxia include headache, dizziness, nausea, and vomiting. Severe symptoms range from dyspnea, altered mental status, cardiac dysrhythmia, ischemia, syncope, seizure, coma to even death. Treatment of asphyxiant poisoning is aggressive supportive care, with control of the airway and ventilation and maintenance of cardiac output. Supportive care is often enhanced by the administration of specific antidotes.

CARBON MONOXIDE POISONING

- CO is a colorless, nonirritant, and odorless gas produced by incomplete combustion of carbonaceous material such as wood, petrol, coal, natural gas, and kerosene.
- The common sources of CO poisoning are car exhaust, clogged chimneys, charcoal burners, poorly maintained and faulty heaters, fires, burning of biomass fuels, gas burners, and industrial emissions.
- Inhalation is the only exogenous exposure route for CO poisoning.
- CO has approximately 210 times more affinity for hemoglobin than oxygen. Binding thus reduces hemoglobin oxygen-carrying capacity and delivery to the tissues. This can result in tissue hypoxia and ischemic injury.
- CO also binds cytochromes, causes endothelial oxidative injury and lipid peroxidation, and triggers inflammatory cascades.
- Clinical symptoms and signs correlate well with measured carboxyhemoglobin percentage (**Table 3**).
- Noncardiogenic pulmonary edema, lactic acidosis, rhabdomyolysis, hyperglycemia, disseminated intravascular coagulation, bullae, and alopecia are other clinical features seen with CO exposure.
- Pre-existing cerebral or cardiovascular disease, anemia, and volume depletion or cardiac failure increase toxicity.
- The diagnosis of acute CO poisoning should be confirmed by an elevated level of carboxyhemoglobin either in arterial or in venous blood.
- Elevation of the blood lactate level is an indication of severity.
- Obtaining an electrocardiogram and cardiac biomarkers in patients with moderate-to-severe CO poisoning is recommended.
- The administration of 100% oxygen will displace CO from hemoglobin and decrease the effective half-life from 4 hours to 40 minutes. The half-life is initially even shorter as hyperventilation and increased cardiac output also increase the rate of elimination.
- CO-poisoned patients should receive a high flow of oxygen for 8 hours, and in case pregnant, it should be for 24 hours.
- Hyperbaric oxygen (HBO) is a therapeutic option for CO-poisoned patients; however, its use cannot be mandated.
- The indications in patients for HBO therapy recommended by the Undersea and Hyperbaric Medical Society are given in **Box 1**.

TABLE 3: Concentrations of carboxyhemoglobin and clinical features.

<10%	Nil (commonly found in smokers)
10–20%	Nil or vague nondescript symptoms
30–40%	Headache, tachycardia, confusion, weakness, nausea, vomiting, collapse
50–60%	Coma, convulsions, Cheyne–Stokes breathing, arrhythmias, ECG changes
0–80%	Circulatory and ventilatory failure, cardiac arrest, death

BOX 1: Indication for hyperbaric oxygen therapy.

- Transient or prolonged loss of consciousness
- Abnormal neurologic signs
- Cardiovascular dysfunction
- Severe acidosis
- Age over 36 years
- CO exposure of ≥24 h
- Carboxyhemoglobin level ≥25%
- Pregnant patients with evidence of fetal distress

CYANIDE POISONING

- Cyanide is one of the most rapidly lethal agents that is found in liquid and gaseous forms. It can lead to death in a few minutes to a few hours.
- Cyanide poisoning may result from a variety of exposures including structural fires consisting of the combustion of wool, silk, synthetic rubber, and polyurethane, which contain carbon and nitrogen to convert into cyanide. Industrial exposures include metal extraction and refining, electroplating, photography, fumigation, medical exposures, and certain foods such as apricot, peach, apple, cherry, and plum as amygdalin, a cyanogenic glycoside.
- Smoking is the most common form of cyanide exposure and may lead to "tobacco amblyopia."
- Intravenous and inhalation of cyanide fumes produce a faster onset of signs and symptoms than exposure via the oral or transdermal route due to fast diffusion into the bloodstream.
- Cyanide mainly inhibits oxidative phosphorylation by blocking the reduction of oxygen to water. This results in cessation of cellular respiration and further results in tissue hypoxia and the depletion of adenosine triphosphate (ATP), thus leading to the production of a severe lactic acidosis.
- At higher concentration of cyanide levels, pulmonary edema is documented and it is believed to be secondary to left ventricular failure and increased pulmonary wedge pressure due to vasogenic response of pulmonary-arteriolar and/or coronary artery.
- Clinical features vary from mild vertigo, headache, dizziness, confusion to seizures, coma, cardiac arrhythmia, apnea, and cardiac arrest.
- Hypotension and bradycardia are pathognomonic for cyanide poisoning.
- Mouth-to-mouth rescue breathing is contraindicated in cyanide poisoning due to the risk of contamination and toxicity to the provider.
- Decontamination is an important part in the management of cyanide exposure through topical and inhalation routes.
- Administer high flow of medical oxygen at the maximum rate.
- The *Cyanide Antidote Kit* contains amyl nitrite, sodium nitrite, and sodium thiosulfate.
- Amyl nitrite is a nitrite-based cyanide antidote which oxidizes hemoglobin to methemoglobin, which complexes with cyanide to form nontoxic cyanmethemoglobin.
- Amyl nitrite, one ampoule (0.3 mL), is inhaled before securing an intravenous access. To be more effective, amyl nitrite must be used in association with oxygen by breaking the ampoule within the oxygen mask.
- Intravenous sodium nitrite of 300 mg given over 2–4 minutes, which forms methemoglobin and attracts cyanide away from inhibited cytochrome oxidase, forms cyanmethemoglobin which allows the resumption of cellular respiration. This antidote should be administered in combination with sodium thiosulfate at the dose of 12.5 g in 50 mL, intravenously over 30 minutes in adults which enhances the activity of rhodanese by donating a sulfur group, thereby increasing the amount of less toxic metabolite thiocyanate, which is renally eliminated.
- Sodium thiosulfate acts more slowly compared to other antidotes because it penetrates the cell and mitochondrial membranes poorly.
- Hydroxocobalamin is a safe and effective antidote given at a dose of 5 g infused over 15 minutes and it detoxifies cyanide into nontoxic cyanocobalamin, which is excreted in the urine.
- It is known to cause a reddish discoloration of the body fluids.

SUMMARY

- About one third of patients with burn injuries have a concomitant inhalation injury.
- CO poisoning should be presumed in any patient who presents following smoke inhalation until it is excluded by a normal carboxyhemoglobin level on CO-oximetry.
- Early intubation is justified for any patient with suspected inhalation injury and signs of respiratory distress.
- Early use of bronchoscopy helps to confirm the diagnosis and grading of inhalation injury.
- The inpatient management of patients with inhalation injury treatment is mainly supportive and consists of monitoring the patient for subsequent development of airway compromise.
- Clearing the airways with a combination of inhaled N-acetylcysteine and heparin is an essential component in the management of patients with inhalation injury.
- CO poisoning is often overlooked.
- Pulse oximetry is often falsely reassuring with normal saturations.
- The fetus is particularly susceptible to the effects of CO intoxication.
- Fetal monitoring in the form of a cardiotocography (CTG) and an obstetric consultation is mandatory for the pregnant victims.
- In case of industrial fire, cyanide toxicity is also suspected.
- Patients with cyanide poisoning will not be cyanotic but will have a cherry-red color due to excess oxygen in the bloodstream.

213
CHAPTER

Iron and Heavy Metals

Sameer Thapa, Anup Raj Upreti

INTRODUCTION

The accumulation of heavy metals above average level that may modulate numerous enzymatic systems resulting in serious consequences in the body is termed as heavy metal poisoning. The sign and symptoms may vary depending upon the nature and quantity of the heavy metals ingested or exposed. The most common heavy metals associated with poisoning are iron, lead, mercury, and arsenic.

IRON

Sources of Iron

Prenatal vitamins, pediatrics multivitamins tablets containing iron.

Absorption

Iron absorbs as elemental iron. The fraction of elemental iron may vary depending upon its preparation: iron has direct corrosive injury on gastrointestinal (GI) mucosa resulting in hemorrhagic necrosis, perforation, and peritonitis. Unbound (free) iron causes:

- Cell membrane toxicity by hydroxyl free radicals-mediated lipid peroxidation
- Increases capillary permeability and both arteriolar and venodilator causing hypotension and venous pooling
- Inhibition of oxidative phosphorylation causing metabolic (lactic) acidosis
- Direct myocardial toxicity and decreases cardiac output
- Oxidative and free radical injury leading to hepatic damage

Clinical Features of Iron Toxicity

- *Asymptomatic:*<20 mg/kg
- *GI symptoms only*: 20–60 mg/kg
- *Severe systemic toxicity*: 60–120 mg/kg
- Potential lethal > 120 mg/kg

Stages of iron toxicity are as follows:

- *Stage I (0–6 hours)*: Direct corrosive effects of iron in the gut causes vomiting, abdominal pain, diarrhea, hematemesis, hematochezia, and fluid loss may result in hypovolemic shock.
- *Stage II (6–24 hours)*: Latent period of apparent improvement contributing to false sense of recovery. During this time iron shifts intracellularly from the circulation.
- *Stage III (12–48 hours)*: Intracellular iron disrupts cellular metabolism with resultant vasodilator shock and third space loss, high anion gap metabolic acidosis (HAGMA), hepatorenal failure and coagulopathy.
- *Stage IV (2–5 days)*: Acute hepatic failure, convulsion, and coma. It resulted from direct action of iron on mitochondria and has a high mortality.
- *Stage V (2–6 weeks)*: Delayed sequelae of iron poisoning, scarring from the initial corrosive injury of GI mucosa characterized by pyloric or proximal bowel stricture resulting which is sometimes associated with obstruction.

Treatment of Iron Toxicity

- *Resuscitation:* Assess airway, breathing, and circulation. Consider nasogastric tube.
- *Treat hypovolemia:* IV crystalloid 10–20 mL/kg boluses to prevent shock from GI losses, vasodilation, and third spacing and replace blood if needed treat coagulopathy with fresh frozen plasma (FFP) and vitamin K. Treat coma, seizure, and metabolic acidosis if they occur.
- *Decontamination*: Whole bowel irrigation with polyethylene glycol–electrolyte lavage solution (PEG-ELS) for significant ingestions (>20 mg/kg of elemental iron, iron tablets identified in X-ray abdomen).
- *Route*: Orally or nasogastric tube.
  - Dose: 2 L/h by continuous infusion (children 25 mL/kg/h) continued until the rectal effluent is clear and there is no radiographic evidence of pill fragments.
  - Injection metoclopramide 10 mg IV in adults (0.1 mg/kg in pediatrics to reduce nausea and increase gastric emptying).
- *Antidote*: Deferoxamine chelation therapy is indicated in the presence systemic toxicity or serum iron level above 500 µg/dL. It chelates iron to form the water-soluble compound ferrioxamine. And also limit the entrance of iron into the cell and chelate intracellular iron. Continue

cardiac monitoring, reconstitute 500 mg of powder with 5 mL of sterile water, and dilute in 100 mL of 0.9% saline or 5% dextrose. IV infusion at 15 mg/kg/h for up to 24 hours reduced if hypotension occurs, may be titrated up to 35 mg/kg/h in severe toxicity. Pregnancy is not a contraindication to deferoxamine. The infusion can be stopped when the patient is clinically stable and the serum iron level is <350 μg/dL. Adverse effects include hypersensitivity, hypotension, (with rapid or high dose IV administration), toxic retinopathy, *Yersinia* sepsis (the ferrioxamine complex is a siderophore that promotes growth).

- *Early exchange transfusions:* Serum iron levels exceeding 1,000 μg/dL.
- *Disposition*: Asymptomatic, ingested <20 mg/kg of elemental iron, normal abdominal radiograph should be observed for 6 hours and can be discharged if he or she remains asymptomatic after 6 hours of observation. The patient who has ingested >20 mg/kg of elemental iron or has pills visible on an abdominal radiograph should receive whole-bowel irrigation. Psychiatric assessment should be performed in adults before discharge from hospital.

LEAD

Sources of Lead

Battery burning, refinery, smelter, fuel combustion, automobile exhaust, and brass making; glassmaking; stripping old paint, and contaminated herbal medications; ingestion of paint chips, lead-laden floor dust, and lead foreign bodies: Lead found in inorganic, organic and leaded gasoline.

Absorption

Lead absorb by inhalation, ingestion and through cutaneous route. Lead binds to sulfhydryl groups, phosphate or carboxyl ligands resulting in inactivation or alteration of enzymes and exerts toxic-most effects in the hematopoietic, neurologic, renal, and reproductive systems. Lead toxicity causes injury to astrocytes, resulting disruption of the blood-brain barrier causes cerebral edema, and seizures, segmental demyelination, and motor axonal degeneration. It interferes with porphyrin metabolism, which contributes to lead-induced anemia. Lead toxicity may cause spontaneous abortion, premature membrane rupture, depressed sperm counts, abnormal or nonmotile sperm, and sterility. Chronic lead toxicity can depress free thyroxine levels without producing clinical hypothyroidism.

Clinical Features of Lead Toxicity

Central Nervous System

- *Acute*: Ataxia, altered mental status, encephalopathy, convulsion, coma, and papilledema.
- *Optic neuritis chronic*: Headache, sleep disturbances, fatigue, irritability, depression, mood swing, and behavior changes memory deficit.
- *Peripheral nervous system*: Wrist drop or foot drop, decreased or absent DTR, paresthesia, and intact sensory function.
- *Gastrointestinal*: Cramping abdominal pain, nausea, vomiting, metallic taste constipation, and diarrhea. *Renal acute*: Fanconi syndrome, renal tubular acidosis
- *Chronic*: Acute kidney impairment, hypertension, and gout.
- *Reproductive*: Impotence, decreased libido, decreased sperm count, and erectile dysfunction.
- *Others*: Myalgia, fatigue, irritability, insomnia, tremor, arthralgia, muscular exhaustibility, anorexia, and bluish black lead line on gums (Burton's line) (**Table 1**).

Treatment of Lead Toxicity

- *Resuscitation*: Assess airway, breathing, and circulation. Provide adequate hydration to maintain urine flow but avoid overhydration which may aggravate cerebral edema.
- *Acute lead encephalopathy*: Aggressive control of ICP *controlled hyperventilation*: $PaCO_2$ 25–30 mm Hg intubation and neurosurgical consultation for invasive monitoring of intracranial pressure.
- *Diuretics*: Mannitol 20%, 1 g/kg IV infusion over 20 minutes
- *Dexamethasone*: 16 mg/kg in divided doses
- *Seizure control*: Treat seizures if they occur. With IV diazepam adult: Up to 10 mg IV slowly, repeat if necessary. Child: 0.1–0.3 mg/kg slowly. Seizure from lead encephalopathy may be resistant to anticonvulsant therapy.
- *Foley's catheterization*: To monitor urinary specific gravity, sediment, and lead level. *Decontamination* with whole-bowel irrigation should be considered.
- *Chelation therapy*: Chelation therapy doses are based on blood lead level, weight, and age.
  - Blood lead level (*BLL) >70 μg/dL or with lead encephalopathy:* dimercaprol or BAL: 75 mg/m^2 deep IM injection q 4 hours for 5 days for children or 4 mg/kg every 4 hours for adults. Contraindicated in patients allergic to peanuts. Followed by ethylenediaminetetraacetic acid ($CaNa_2EDTA$) 1,500 mg/m^2/day (approximately 50–75 mg/kg/day). Start 4 h after BAL.

TABLE 1: Features of lead toxicity.

Level (μg/dL)	*Adults symptoms*	*Children symptoms*
10	None	Decreased IQ, hearing and growth
20	Increased protoporphyrin, no symptoms	Decreased nerve conduction velocity Increased protoporphyrin
30	Increased blood pressure Decreased hearing	Decreased vitamin D metabolism
40	Peripheral neuropathies Nephropathy infertility (men)	Decreased hemoglobin synthesis
50	Decreased hemoglobin synthesis	Lead colic
70	Anemia	Anemia, encephalopathy, nephropathy
100	Encephalopathy	Death

- *Blood lead level BLL of >69 μg/dL with* less severity: $CaNa_2EDTA$ 50 mg/kg/day or 1,000 mg/m^2/day, given in two to four divided doses for up to 5 days.
- *Blood lead levels of 45–69 μg/dL in patients without vomiting or central nervous system (CNS)*: oral succimer [2,3-dimercaptosuccinic acid (DMSA)]. The initial dose of DMSA is 10 mg/kg every 8 hours for 5 days, then 10 mg/kg every 12 hours for 14 days.
- *Blood lead level <45 μg/dL*: No need for chelation

Disposition

Acute lead exposure with CNS symptoms and children with a BLL of 69 μg/dL or higher: Hospitalize and start chelation therapy. Asymptomatic children and adults—repeat BLL after 2 weeks to ensure decreasing levels. Ingested a single lead foreign body passes harmlessly.

MERCURY

Source of Mercury

Elemental salts battery and thermometer manufacture; dentistry; jewelry and lamp manufacture; photography; mercury mining; manufacture of scientific instruments; fur processing; tannery work; chemical laboratories; and manufacture of explosives, fireworks, disinfectants, button batteries, inks, and vinyl chloride. Contaminated seafood; embalming; manufacture of fungicides, bactericides, handling of insecticides; and pesticides and coated seeds.

Mercury Absorption

Mercury absorb by inhalation, ingestion and through cutaneous route.

Form: Inorganic mercuric salts

Elemental (metallic) mercury: Liquid, vapor organic (alkyl) mercury. Mercury binds to sulfhydryl (SH) groups resulting in enzyme inhibition and cellular toxicity.

Mercury causes: Renal tubular damage by immune reaction and direct damage, direct corrosive effect on GI tract and hemorrhage. Mercury causes contact dermatitis by an immune reaction, and also causes hypertension and tachycardia by inhibiting catechol-o-methyltransferase. Mercury is a direct pulmonary irritant. Atrophy of the cerebellum, postcentral gyri, and calcarine areas of the brain causing ataxia and sensory and visual field disturbances.

Clinical Features of Mercury Toxicity

Risk assessment: Severity of toxicity is determined by mercury form and route of exposure. Air-borne exposure of volatile elemental mercury>10 mg/m^3 is considered life-threatening.

Inorganic mercuric salts: Fatal oral dose of mercuric chloride: 1–4 g

Organic mercury: Fatal oral dose of methylmercury: 10–60 mg/kg

Acute inhalation of metallic mercury: Chest tightness, respiratory distress ARDS, burning in mouth and throat, nausea, vomiting, bloody diarrhea, and renal tubular necrosis

Acute aspiration of liquid metallic mercury: Tracheobronchial hemorrhage and ARDS

Acute Ingestion of inorganic mercury salts: Hemorrhagic gastroenteritis, abdominal pain, intestinal necrosis, shock, and acute tubular necrosis (ATN).

Chronic inhalation of metallic mercury: Metal fume fever, renal dysfunction, skin changes, and neuropsychiatry disturbance (fatigue, insomnia, anorexia, and memory loss).

Chronic inhalation of inorganic mercury: Neurasthenia, erethism, and acrodynia.

Organomercury exposure: Ataxia, tremor, hyperreflexia, spasticity, hearing loss, dysarthria, and visual field defect. Swallowing of liquid metallic mercury does not produce adverse effects unless the tract contains fistulas or delay gut motility because of poor GI absorption.

Treatment of Mercury Toxicity

Resuscitation: Assess airway, breathing, and circulation. For acute inhalation, remove patient from the source, manage acute pneumonitis and pulmonary edema if necessary. Suction and postural drainage are indicated in cases of acute aspiration of metallic mercury. Anticipate gastroenteritis and treat shock aggressively with IV fluids.

Chelation therapy: BAL is contraindicated for patients poisoned with organic mercury compounds. BAL is used for clinically significant acute inorganic mercury intoxication. BAL: 5 mg/kg IM stat, then 2.5 mg/kg IM every 8–12 h for 1 day and then 2.5 mg/kg IM every 12–24 hours until clinical improvement occurs days. Others: DMPS, DMSA, and D-penicillamine.

Disposition

Acute intoxication and features of neurotoxicity require decontamination and admission for supportive treatment. Self-inject metallic mercury needs admission for surgical debridement. Asymptomatic and fish eaters should abstain from eating locally caught fish and can be observed closely with monthly urine testing as outpatients.

ARSENIC

Sources of Arsenic

Homeopathic medicines, insecticides; rodenticides; herbicides; coal combustion and uranium mining; wood preservatives; veterinary medicines; and semiconductor industry.

Absorption

Arsenic absorb by ingestion, inhalation and through cutaneous route. Arsenic available as elemental arsenic which is poor water soluble and also non toxic. Inorganic trivalent arsenite is more toxic. Arsine is a organic and gaseous form. Arsenic binds to sulfhydryl groups, inhibiting the enzymes such as lactate dehydrogenase and glyceraldehyde-3-phosphate dehydrogenase which involves in glycolysis. In chronic exposures, arsenic redistributes to the liver, kidneys, lungs, nervous system, spleen, hair, and nails, however, it does not easily cross blood-brain barrier. Arsenic crosses the

placenta and has produced teratogenicity in humans. The chemical warfare agent's lewisite (dichlorvos 2-chlorovinyl arsine) causes severe irritation and necrosis of eyes, skin, and airways.

Clinical Features of Arsenic Toxicity

Arsenic risk assessment: Ingestion of <0.05 mg/kg may cause mild GI symptoms. Ingestion of >1 mg/kg is potentially fatal. Chronic intoxication usually takes 10+ years to occur from artesian water. *Children:* Any ingestion of arsenic insecticide should be considered as potentially fat.

Acute exposure to arsine gas: Hemolysis associated with renal tubular injury

Gastrointestinal: Hypersalivation and metallic or garlic taste, nausea, vomiting, abdominal pain, watery diarrhea, hematemesis and hematochezia, and pancreatitis

Cardiovascular: Hypotension, tachycardia, arrhythmias, and prolonged QT interval

Neurological: Headache, drowsiness, delirium, coma, encephalopathy, and seizures. Peripheral neuropathy

Skin: Cutaneous lesions (hyperkeratosis of palms and soles and hyperpigmentation), nail changes (Mee's lines), painful sensorimotor neuropathy, and malignancies of the skin of bladder

Others: Hepatitis, rhabdomyolysis, hemolytic anemia, pancytopenia, unilateral facial nerve palsy, pancreatitis, pericarditis, pleuritis, and fetal demise

Treatment of Arsenic Toxicity

Resuscitation: Assess airway, breathing, and circulation.

Treat hypovolemia: IV crystalloid 10–20 mL/kg, if response is not adequate, start noradrenaline [dose—0.15 mg/kg in 50 mL D5W at 1–10 mL/h (0.05–0.5 μg/kg/min)]. Correct any electrolyte abnormality—potassium, calcium, and magnesium. Avoid drugs that prolong QT interval. Continuous cardiac monitoring—treat coma and arrhythmia if occur, prolonged QT, Torsades de pointes, ventricular tachycardia, and ventricular fibrillation.

Treat seizures: Rule out dysrhythmia, managed with benzodiazepine; lorazepam 0.1 mg/kg max 4 mg; diazepam 0.15 mg/kg max 10 mg; and midazolam 0.2 mg/kg max 10 mg.

Decontamination: Whole bowel irrigation with PEG if the patient is cooperative and recent ingestion (<1 hour) or radiopaque material is visualized on an abdominal radiograph. It requires one nurse—probably for the next 6 hours, administer PEG solution at 2 L/h by continuous infusion (children 25 mL/kg/h). Given metoclopramide (avoid phenothiazine) to reduce nausea and increase gastric emptying.

Hemodialysis removes arsenic in the setting of acute renal failure.

Exchange transfusions or plasma exchange can be considered early after an arsine exposure.

Chelation therapy: Chelation is indicated when there is history of exposure in a symptomatic patient. *Drug of choice*—capsule succimer 10 mg/kg q8h × 5 days, then q12 h for 14 days. If oral administration is not possible, then *dimercaprol* 3 mg/kg IM every 4 hours for 48 hours, then twice daily for 7–10 days.

Disposition

Chronic intoxication can be managed as an outpatient, patients who are asymptomatic at 12 hours postpotential ingestion are not poisoned and may be medically cleared. Those who are symptomatic require aggressive supportive care and chelation until symptoms resolve. Follow-up bloods will be required to monitor ongoing complications if they survive the acute phase. Also warn patients on discharge about ascending neuropathy.

INVESTIGATIONS

History, physical examination along with important laboratory and radiological investigations are important for diagnosing toxicity due to heavy metal poisoning (**Table 2**).

OTHER METAL POISONING

Thallium Poisoning

Thallium poisoning presents with extreme drowsiness (somnolence), nausea, vomiting, abdominal pain, and bloody vomiting (hematemesis). Other important features are loss of hair especially scalp hair (alopecia); rapidly progressive and painful sensory polyneuropathy; motor neuropathy; cranial nerve palsies; seizures; impaired ability to coordinate voluntary movements (cerebellar ataxia); and/or mental retardation. Some patients may have eye symptoms including optic nerve atrophy, inflammation of the optic nerve (retrobulbar neuritis), and impaired functioning of the muscles of the eyes (ophthalmoplegia). In some cases, progression of thallium poisoning to renal and cardiac failure, confusion, psychosis, organic brain syndrome, and/or coma also noted.

Chromium Poisoning

Chromium is used in the manufacturing unit of cars, glass, pottery, and linoleum. Lung and respiratory tract cancer as well as kidney diseases manifest due to exposure of too much chromium in workers of these manufacturing units. Clinical features of overexposure to chromium are GI symptoms, such as diarrhea and vomiting, often with blood, severe dehydration electrolyte disorders, acidosis, and shock.

Cadmium Poisoning

Cadmium is used in the manufacturing units of electroplating, batteries, vapor lamps.

Characteristics of the cadmium exposure are as follows: symptoms develop 2–4 hours after exposure. Overexposure of cadmium causes fatigue, headaches, nausea, vomiting, abdominal cramps, diarrhea, and fever. Patient may present with breathlessness due to development of pulmonary edema and in later stage emphysema. Increased salivation; yellowing of the teeth; tachycardia, anemia, cyanosis, due to insufficient oxygen supply to these tissues; and anosmia, renal tubular dysfunction leads to proteinuria, and osteomalacia.

TABLE 2: Recommended work-up for heavy metal poisoning.

Arsenic	*Iron*	*Lead*	*Mercury*
• CBC: Anemia, leukocytosis or leukopenia, and RBC basophilic stippling • Renal function tests: Proteinuria, hematuria, and pyuria • LFT: The alanine transaminase, aspartate transaminase, and bilirubin levels may be elevated • Urine level: 24-hour urinary excretion of arsenic >100 µg • Blood level: Blood arsenic level is useful if the patient is anuric. Level > 70 µg/L suggests poisoning • X-ray abdominal: Radiopaque intestinal metallic flakes • Hair and nail level: Hair and nail specimens can confirm the diagnosis • Echo: Cardiomyopathy is suspected • In cases of chronic arsenic poisoning, 12-lead ECG: Prolonged QTc interval	• Serum iron level: (3–5 h postingestion) <350 µg/dL associate with minimal toxicity, 350–500 associates with moderate toxicity and >500 µg/dL predicts severe systemic toxicity • Radiography: X-rays chest and abdominal (can confirm and monitor ingestion but some preparations are not radio-opaque—this is not a rule out test) • Biochemistry: CBC, LFTs, electrolytes, serum glucose level, RFT, ABG, and coagulation studies	• Blood lead level: BLL = 10 µg/dL or higher considered toxic • CBC: Low Hb • PBS: Normochromic or hypochromic and microcytic RBC, basophilic stippling • RFT • LFT • Radiograph: X-ray abdomen and pelvis, plain radiographs of the wrist and knees: horizontal metaphyseal "lead bands" or "lead lines" • CT head: To rule out cerebral edema due to acute lead encephalopathy. In cases of altered mental status, seizures, or coma	• Blood mercury level >10 µg/L require further investigations for possible exposure • Radiograph: History of injection or ingestion of metallic mercury • Others: ABG, electrolytes, glucose, LFT, and RFT

(ABG: arterial blood gas; CBC: complete blood count; ECG: electrocardiogram; LFT: liver function test; PBS: peripheral blood smear; RFT: renal function test)

SUMMARY

Accumulation of heavy metals, in toxic amounts, in the soft tissues of the body gives rise to features of heavy metal poisoning. Severity of the clinical features varies according to the amount of metal accumulated. Few heavy metals (zinc, copper, chromium, iron, and manganese) are essential for body in very small amount but serious damage may occur, if they present in concentrations sufficient to cause poisoning. Lead, mercury, arsenic, and cadmium most commonly associated with poisoning of humans. Humans exposed to toxic doses of heavy metals because of industrial exposure, air or water pollution, foods, medicines, improperly coated food containers, or the ingestion of lead-based paints. This is very important for the emergency physician to be aware about the heavy metal toxicity, their features and management.

CHAPTER

Dyshemoglobinemias

Gireesh Kumar KP

INTRODUCTION

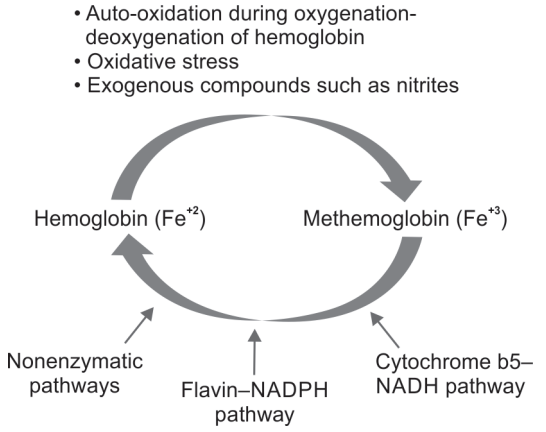
Dyshemoglobinemias are clinical disorders in which the hemoglobin is functionally altered and loses the ability of carrying oxygen properly. The most clinically relevant dyshemoglobinemias are methemoglobinemia, sulfhemoglobinemia, and carboxyhemoglobin (CO-Hb).

METHEMOGLOBINEMIA

Clinically significant methemoglobinemia (congenital or acquired) develops when red blood cells (RBCs) contain methemoglobin at levels higher than 1%. is an altered state of hemoglobin in which the ferrous (Fe^{++}) irons of heme are oxidized to the ferric (Fe^{+++}) state [i.e., hemoglobin with its iron in the ferric (oxidized; Fe^{+++}) state (**Fig. 1**)], which cannot reversibly bind oxygen and, oxygen dissociation curve is left-shifted, making it more difficult to release O_2 (**Fig. 2**).

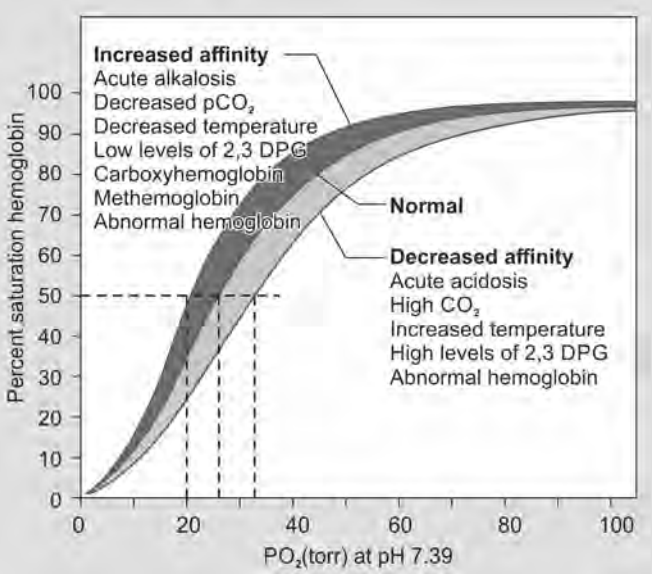
The effect is that patients with acutely increased concentrations of methemoglobin have a functional anemia (i.e., the amount of functional hemoglobin which can carry oxygen is less than the measured level of total hemoglobin). The methemoglobin-containing hemoglobin cannot deliver oxygen to tissues and the remaining oxyhemoglobin has very high oxygen affinity, resulting in impaired oxygen delivery to the tissues, which leads to severe tissue hypoxia.

Normal concentration of methemoglobin in body <1% of total hemoglobin: Auto-oxidation of hemoglobin to methemoglobin occurs spontaneously at a slow rate, each day converting 0.5–3% of the available hemoglobin to methemoglobin. This auto-oxidation, along with the subsequent reduction of methemoglobin, acts to maintain a steady-state level of methemoglobin). When the level is >10% (or 1.5 g/dL absolute concentration of methemoglobin), central cyanosis occurs. There are two types of methemoglobinemia: (1) Congenital; and (2) Acquired.



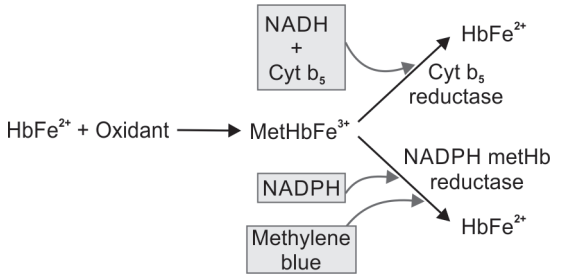
(NADH: nicotinamide adenine dinucleotide; NADPH: nicotinamide adenine dinucleotide phosphate)

FIG. 1: Pathophysiology methemoglobinemia [ferrous (Fe^{++}) irons of heme are oxidized to the ferric (Fe^{+++}) state].



(DPG: diphosphoglycerate)

FIG. 2: Left shift of curve reduces the amount of oxygen delivered to tissues.



(NADH: nicotinamide adenine dinucleotide; NADPH: nicotinamide adenine dinucleotide phosphate)

FIG. 3: Congenital methemoglobinemia (enzymatic reduction of methemoglobin back to normal hemoglobin).

Congenital Methemoglobinemia

There is diminished enzymatic reduction of methemoglobin back to normal hemoglobin [also known as ferrohemoglobin; i.e., hemoglobin with its iron in the ferrous [reduced; Fe^{++}] state] or a mutant globin which facilitates spontaneous oxidation of ferrous iron to ferric state (**Fig. 3**). Patients have lifelong cyanosis but are generally asymptomatic.

Type I disease: Most of the cases are type I, in which the functional deficiency of cytochrome b5 reductase is limited to erythrocytes. Methemoglobinemia and the resulting cyanosis (and possibly polycythemia) are the only clinical features.

Type II disease: In type II cytochrome b5 reductase deficiency, which represents 10–15% of cases of enzymopenic congenital methemoglobinemia, cytochrome b5R is deficient in all cells. They can have cyanosis with severe developmental abnormalities; most affected infants die in the first year of life.

Acquired Methemoglobinemia

Acquired methemoglobinemia occurs due to the ingestion of some drugs or agents that cause an increase in the production of methemoglobin. It can be a severe problem or even a fatal illness. Methemoglobinemia can be caused by nitrites, nitroprusside, nitroglycerin, chlorates, sulfonamides, aniline dyes, nitrobenzene, antimalarials, dapsone, metoclopramide, and phenazopyridine (**Box 1**). Dapsone and topical anesthetic agents (e.g., lidocaine, benzocaine, prilocaine) are the most common precipitating agents of acquired methemoglobinemia. Drugs with oxidant properties (e.g., benzocaine, lidocaine, dapsone) are commonly added to heroin, cocaine, and other illicit drugs which can also cause unexplained acquired methemoglobinemia in drug abusers. Dapsone is used commonly for the treatment of leprosy, malaria, and a variety of blistering skin diseases, including dermatitis herpetiformis.

Methylene blue (MB) is itself an oxidant at doses >7 mg/kg and thus may cause methemoglobinemia in susceptible patients. While MB is a recognized treatment for methemoglobinemia, it may worsen the clinical status of persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency because it can trigger acute hemolysis that can further reduce oxygen delivery to the tissues. In high doses, MB can paradoxically increase methemoglobinemia.

Methemoglobin is produced by oxidation of the heme iron moieties to the ferric state, leading to a characteristic bluish-brown muddy color of skin and mucous membranes resembling cyanosis. Methemoglobin has such high oxygen affinity that virtually no oxygen is delivered to tissues. Methemoglobinemia can cause symptoms of cerebral ischemia at levels >15%; levels >60% are usually lethal.

BOX 1: Medications and chemicals that can cause acquired methemoglobinemia.

- Dapsone
- Clofazimine, chloroquine, primaquine
- Amino salicylic acid (also called p-amino salicylic acid or 4-aminosalicylic acid)
- Local anesthetics, topical creams, and sprays such as benzocaine (in teething rings and ointments), lidocaine, prilocaine
- Quinones, sulfonamides
- Menadione, metoclopramide
- Methylene blue
- Nitroglycerin, phenacetin, phenazopyridine
- Rasburicase

Chemicals and environmental substances:

- Naphthalene (used in mothballs)
- Nitrates and nitrites (e.g., amyl nitrite, farryl nitrite, sodium nitrite, nitrate- and nitrite-containing foods, nitric oxide, well water)
- Paraquat (used in herbicides)
- Resorcinol (used in resin melting and wood extraction)
- Antifreeze, benzene derivatives (used as solvents)
- Acetanilide (used in varnishes, rubber, and dyes)
- Anilines and aniline dyes such as diaper and laundry marking inks, leather dyes, red wax crayons
- Chlorates and chromates (components used in chemical/industrial synthesis)
- Hydrogen peroxide (used as a disinfectant and cleaner)
- Naphthoquinone (used in chemical synthesis)
- Nitrobenzene (used as a solvent)

Inherited disorders (extremely rare):

- Cytochrome b5-reductase deficiency
- Hemoglobin M disease

Clinical Features

Headache, fatigue, lethargy, dyspnea, tachycardia, dizziness, and hypotension due to the vasodilating properties of nitrates as well as tissue hypoxia. Seizures also may occur.

Cyanosis is clinically detected when the absolute concentration of methemoglobin reaches >1.5 g/dL, equivalent to methemoglobin percentage of around 15% at normal hemoglobin concentrations (hypoxic cyanosis occurs when the concentration of unsaturated hemoglobin exceeds 4 g/dL). Levels of methemoglobin >30–40 % are considered "life-threatening" and may be fatal. Acquired methemoglobinemia can become symptomatic when methemoglobin level is >10% of the total hemoglobin. Levels of methemoglobin > 30–40% are considered "life-threatening" and are associated with severe hypoxia and may lead to death.

Diagnosis

The diagnosis is suggested in patients with a normal oxygen tension [by arterial blood gas (ABGs)] and generalized cyanosis (corresponding to a methemoglobin level of 15% or more) that does not respond to oxygen. Pulse oximetry is not accurate and not reliable in patients with high methemoglobin levels. However, an abnormal saturation value in a cyanotic and relatively asymptomatic patient may suggest the presence of an elevated methemoglobin fraction. Clinical cyanosis and normal arterial oxygen tension by arterial blood gas are highly suggestive of methemoglobinemia.

Methemoglobin and Routine Pulse Oximeter

Methemoglobin absorbs at both 660 and 940 nm. Methemoglobinemia should be considered in patients with cyanosis and normal PaO_2. The level of methemoglobin increases up to 20% and SaO_2 drops by about one half of the methemoglobin percentage. At higher methemoglobin levels, SaO_2 falls to 85% regardless of the actual percentage of oxyhemoglobin, thus leading to over- or underestimation of the true SaO_2.

Inaccuracy of routine pulse oximetry and blood gas analysis: Routine pulse oximetry is mostly inaccurate for monitoring oxygen saturation in the presence of methemoglobinemia and should not be depended upon to make the diagnosis of this disorder.

The diagnosis of methemoglobinemia is confirmed by direct measurement of methemoglobin by a multiple wavelength co-oximeter. Measurement of greater numbers of wavelengths enables the instrument of CO-Hb, methemoglobin, other hemoglobin moieties, and "background" light-absorbing species. Optimally, methemoglobin can be detected by the co-oximeter and confirmed by the specific Evelyn–Malloy method. This type of assay involves the addition of cyanide, which binds to the positively charged methemoglobin, and eliminating the peak at 630–635 nm in direct proportion to the methemoglobin concentration.

The characteristic muddy appearance of freshly drawn blood can be a critical clue: The most important finding is the development of cyanosis in the presence of a normal arterial pO_2 and/or the presence of "chocolate brown blood." Symptoms of methemoglobinemia are proportional to the methemoglobin level in the blood and include skin color changes and blood color changes at levels up to 15%. As methemoglobin levels rise >15%, neurologic and cardiac symptoms arise as a consequence of severe tissue hypoxia. Levels >70% are usually fatal (**Table 1**).

The best diagnostic test is methemoglobin assay. The standard method of assaying methemoglobin uses a microprocessor-controlled, fixed wavelength co-oximeter. This device interprets all readings in the 630-nm range as methemoglobin; thus, false positives may occur in the presence of other pigments, including sulfhemoglobin, MB, and certain drugs. Sulfhemoglobin, in concentrations >0.5 g/dL, also causes "cyanosis" with a normal PaO_2 and may be erroneously documented as methemoglobin. Sulfhemoglobin can be distinguished from methemoglobin by virtue of its peak absorption at 620 nm which, unlike methemoglobin, is not abolished by the addition of cyanide.

- *Blood investigations to rule out hemolysis*: Complete blood count, reticulocyte counts, lactate dehydrogenase (LDH), indirect bilirubin, peripheral blood smear, haptoglobin.

TABLE 1: Toxicity in acute acquired methemoglobinemia.

Methemoglobin level percent	*Symptoms**
0–3	Normal range for adults
3–12	Minimal level associated with clinical cyanosis, slight discoloration (e.g., pale, gray, blue) of the skin
3–20	Cyanosis present, usually not symptomatic unless pre-existing condition present
20–50	Mild-to-moderate hypoxemia symptoms†
50–70	Severe, life-threatening hypoxemia symptoms‡
>70	Fully cyanosis and usually fatal

*Conditions such as anemia, heart, and lung disease may exacerbate toxicity.
†Headache, lightheadedness, fatigue, tachycardia, dyspnea, and lethargy.
‡Abnormal cardiac rhythms, respiratory depression, altered sensorium, coma, shock, and seizures.

- *Laboratory tests for end-organ damage*: Liver function tests (LFT), electrolyte levels, blood urea nitrogen (BUN), creatinine.
- Blood levels of nitrites and other offending drugs
- ABG
- Chest X-ray to exclude pulmonary or cardiac disease
- Potassium cyanide test can be done to distinguish methemoglobin from sulfhemoglobin.

Treatment

Take care of airway, breathing, and circulation and intervene if needed. Administration of supplemental oxygen to be started for all patients with cyanosis.

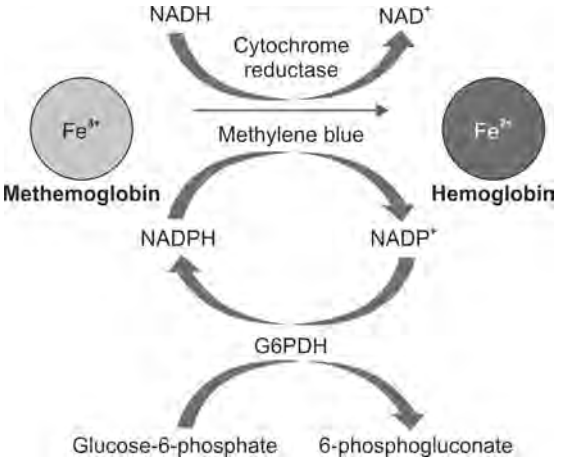
Cytochrome b5 Reductase Deficiency

Treatment of cyanosis in individuals with type I and II cytochrome b5 reductase deficiency is indicated only for cosmetic reasons, if so desired. Treatment options include MB orally at a dose of 100–300 mg/day or ascorbic acid (vitamin C), typically 1,000 mg three times per day; riboflavin (vitamin B2) at a dose of 20–30 mg/day has also been used with some success.

Infants with methemoglobinemia due to metabolic acidosis must be given IV hydration and bicarbonate to reverse the acidosis. The NADPH-dependent methemoglobin reductase enzyme system needs glucose for the clearance of methemoglobin. Therefore, IV hydration with dextrose 5% in water (D5W) is often useful. Vegetables such as spinach, carrots, beets, borage, and chard are high in nitrite or nitrate content and should be avoided by susceptible patients. IV hydration and bicarbonate (for metabolic acidosis) should be given. Cimetidine may be useful in dapsone-induced methemoglobinemia to prevent further formation of its metabolite.

Acquired Methemoglobinemia

Discontinue the drugs which can cause methemoglobinemia. After discontinuation of the causative agent, methemoglobin returns to baseline levels within 36 hours. In lesser degrees of methemoglobinemia (i.e., an asymptomatic patient



(G6PDH: glucose-6-phosphate dehydrogenase; NADH: nicotinamide adenine dinucleotide; NADP: nicotinamide adenine dinucleotide phosphate; NADPH: nicotinamide adenine dinucleotide phosphate)

FIG. 4: Methylene blue for the management of methemoglobinemia.

with a methemoglobin level <20%), no therapy other than discontinuation of the offending agent(s) may be required. If the patient is symptomatic or if the methemoglobin level is >20%, which is often the case in deliberate or accidental overdoses or toxin ingestion, specific therapy is urgently indicated. Medications: MB and ascorbic acid (vitamin C). *IV injection of 1–2 mg/kg of MB in 5 minutes is an effective emergency therapy* (up to a maximum of 50 mg in adults, adolescents, and older children) as a 1% solution in IV saline over 3–5 minutes (**Fig. 4**). The response is usually rapid; the dose may be repeated in 1 hour if the methemoglobin level is still high (e.g., >20%) by co-oximetry 1 hour after the initial infusion or if the methemoglobin level is rising rapidly due to prolonged absorption of the implicated agent from topical or enteric sites. Caution should be exercised to avoid overdosage because large (>7 mg/kg) cumulative doses of MB can cause dyspnea and chest pain as well as hemolysis in some susceptible subjects. Milder cases and follow-up of severe cases can be treated orally with *MB* (60 mg slow IV 3–4 times per day) or ascorbic acid (300–600 mg/day).

Methylene blue should not be used in patients with G6PD deficiency, since the reduction of methemoglobin by MB is dependent upon NADPH generated by G6PD. As a result, MB is not only ineffective, but also dangerous since MB has an oxidant potential that can produce hemolysis in G6PD-deficient patients, precipitating acute hemolysis, thus further decreasing oxygen delivery. Use Vitamin C here as a single agent: 300–1,000 mg/day orally in divided doses. MB is also not useful in patients with hemoglobin M (Hb M).

Methylene Blue and Serotonin Syndrome

Methylene blue is a potent, reversible inhibitor of monoamine oxidase A (MAO-A), an enzyme responsible for breaking down serotonin in the brain. Usage of MB in patients taking serotonergic medications can result in high, occasionally fatal, levels of serotonin in the brain (i.e., serotonin syndrome). Avoid using MB concurrently with serotonergic psychiatric drugs, unless such usage is absolutely needed for life-threatening or urgent conditions. MB may increase central nervous system serotonin levels as a result of MAO-A inhibition, thus increasing the risk of serotonin syndrome.

Exchange Transfusion

Severely affected patients or G6PD-deficient patients can be treated with blood transfusion, exchange transfusion (which replaces abnormal hemoglobin with normal hemoglobin), and/or hyperbaric oxygen (HBO).

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy is another option for patients in whom MB treatment is ineffective or contraindicated. HBO therapy allows tissue oxygenation facilitated by oxygen dissolved in plasma, rather than through hemoglobin-bound oxygen.

SULFHEMOGLOBINEMIA

Sulfhemoglobin is a green-pigmented molecule with a sulfur atom incorporated into the porphyrin ring, which can reduce oxygen affinity that leads to ineffective oxygen transport. Sulfhemoglobin, also in the ferric state, additionally has a sulfur atom incorporated in the hemoglobin. Sulfhemoglobin cannot be converted back to normal Hb A; changes persist for the life of the RBC. Treatment is only prevention by avoidance of exposure of the offending agent.

Causes

Sulfhemoglobinemia is a rare disease which can result from exposure to any substance containing a sulfur atom with the ability to bind to hemoglobin. Sulfhemoglobinemia can be produced by ingestions of phenacetin, dapsone, sumatriptan, and sulfonamides.

Long-term metoclopramide ingestion has also been reported as a cause of sulfhemoglobinemia. Short-term, high-dose metoclopramide treatment with N-acetylcysteine can also cause sulfhemoglobinemia.

It is also associated with industrial chemicals, such as trinitrotoluene, hydroxylamine sulfate, dimethyl sulfoxide, and hydrogen sulfide.

Clinical Features

When comparing with methemoglobinemia, in sulfhemoglobinemia tissue oxygen delivery is somewhat maintained by a rightward shift of the oxygen dissociation curve by decreasing the oxygen affinity of the unaffected hemoglobin. The rightward shift allows for easier oxygen unloading in tissues. Although patients may have a somewhat same percentage of hemoglobin effected as methemoglobinemia patients, sulfhemoglobinemia patients have less severe clinical symptoms because of the difference in their effects on the oxygen dissociation curve.

Diagnosis

Severe sulfhemoglobinemia should be considered in patients presenting with breathlessness oxygen desaturation and cyanosis, especially when methemoglobinemia is excluded. Unlike methemoglobinemia, which can be reversible with

a known antidote, MB, sulfhemoglobinemia can produce irreversible desaturation with no known antidote. Therefore, the blood level of sulfhemoglobin declines gradually over a period of weeks.

Hemoximeters use multiple wavelengths, which can determine the concentrations of oxyhemoglobin, deoxyhemoglobin, CO-Hb, and methemoglobin. Some devices may not distinguish between methemoglobin and sulfhemoglobin because of their similar absorption peaks. Some devices, such as the Chiron Rapidlab 865, indicate the presence of sulfhemoglobin but cannot quantify the concentration of sulfhemoglobin. The laboratory measurement of sulfhemoglobin relies on an absorption peak at 620 nm, which, unlike methemoglobin, can even persist after the addition of cyanide or dithionate.

Treatment

Many patients with sulfhemoglobinemia may also have associated methemoglobinemia. There is no specific treatment available for sulfhemoglobinemia. Treatment is directed at reversing the methemoglobinemia, if present. Severe toxicity may require exchange transfusion or packed red blood cells (PRBC) transfusion.

CARBOXYHEMOGLOBINEMIA—CARBON MONOXIDE POISONING

Carbon monoxide (CO) is a colorless, tasteless, odorless, and nonirritating gas formed by hydrocarbon combustion. The concentration in atmospheric for CO is generally <0.001%, but it may be more in urban areas or enclosed environments. CO binds to hemoglobin with a very high affinity than oxygen, forming CO-Hb and resulting in impaired oxygen transport and utilization. CO can also produce an inflammatory cascade that may lead to central nervous system (CNS) lipid peroxidation and delayed neurologic sequelae (DNS).

Causes

Fire-related smoke inhalation is the major cause of CO poisoning. Other potential sources of CO are poorly functioning heating systems, improperly vented fuel-burning equipment (kerosene heaters, charcoal grills, camping stoves, gasoline-powered generators), and motor vehicles working in poorly ventilated areas (e.g., ice rinks, warehouses, parking garages). Methylene chloride (dichloromethane) is an industrial solvent and a component of paint remover. Inhaled or ingested methylene chloride is converted to CO by the liver and can also cause CO toxicity in the absence of ambient CO.

Carbon monoxide diffuses very rapidly across the pulmonary capillary membrane and binds to the iron moiety of heme with around 240 times more affinity of oxygen. Once CO binds to the heme, an allosteric change occurs that greatly reduces the ability of the other three oxygen-binding sites to release oxygen to peripheral tissues. This leads to a leftward shift of the oxyhemoglobin dissociation curve and impairment in tissue oxygen delivery. CO also reduces the peripheral oxygen utilization. Around 10–15% of CO is extravascular and bound to molecules such as myoglobin, cytochromes, and NADPH reductase, which leads to an impairment of oxidative phosphorylation at the mitochondrial level.

Nonsmokers may have around 3% CO at baseline; smokers may have levels of 10–15%. Severe chronic obstructive pulmonary disease (COPD) patients can also develop a modest but significant elevation in CO-Hb levels compared with a normal individual.

The half-life of CO for a patient breathing room air is about 250–320 minutes, for a patient breathing high-flow oxygen via a nonrebreathing face mask is about 90 minutes, and with 100% HBO is about 30 minutes.

Clinical Features

Mild-to-moderate Carbon Monoxide Toxicity

Patients present with headache (the most common presenting symptom), nausea, dizziness, and malaise. Patients may also present with symptoms ranging from mild confusion to coma. Some may have a "cherry red" appearance of the lips.

Severe Carbon Monoxide Toxicity

Severe CO toxicity can present with neurologic symptoms, such as seizures, syncope, or coma; cardiovascular manifestations, such as myocardial ischemia, ventricular arrhythmias, and lung problems such as breathlessness and pulmonary edema; and metabolic disorder such as profound lactic acidosis.

Delayed Neuropsychiatric Syndrome

In nearly 40% of patients with severe CO toxicity, a syndrome of DNS can arise after apparent recovery within a year. The development of DNS poorly correlates with CO-Hb levels, although a majority of cases are associated with loss of consciousness during acute intoxication. The clinical features of this syndrome are variable degrees of cognitive deficits, personality changes, movement disorders, and focal neurologic deficits. DNS normally occur within 20 days of CO toxicity and may persist for a year or longer.

Diagnosis

Acute CO poisoning is usually suspected on the basis of history and physical examination because the diagnosis of chronic CO intoxication is very much difficult without strong clinical suspicion. Routine pulse oximetry (SpO_2) *cannot* screen for CO intoxication, as it cannot differentiate CO-Hb from oxyhemoglobin. *The diagnosis of CO poisoning is based upon a high* CO-Hb *level measured by co-oximetry of an ABG sample.* In hemodynamically stable patients, venous samples are also accurate and commonly used to avoid arterial prick and it may be very useful when handling a large number of patients in major disasters. Nonsmokers can have up to 3% of baseline CO-Hb; in smokers, this is about 10–15%. Levels more than these values are diagnostic of CO poisoning. A CO-Hb measurement is essential for diagnosis, but levels may not correlate with the degree of poisoning and are not predictive of DNS.

Caution: Treatment with hydroxocobalamin (as might be given for suspected cyanide exposure from smoke inhalation)

can interfere with the measurement of CO-Hb concentration which may lead to inaccurate results. In patients with possible cyanide exposure (e.g., brought to the hospital from a fire area), clinicians should ask about the treatment history that whether hydroxocobalamin was given.

Blood PO_2 levels may be normal because PO_2 reflects O_2 dissolved in the blood, and this process is not affected by CO. In contrast, hemoglobin-bound O_2 (which normally comprises 98% of arterial O_2 content) is severely reduced in the presence of CO-Hb.

ECG and cardiac enzymes are to be done to rule out cardiac ischemia.

Computed tomography (CT) of the head may be asked to rule out other causes of loss of consciousness. CO poisoning may cause hemorrhagic infarction of the globus pallidus and, rarely, the deep white matter.

Treatment

Take care of airway, breathing, and circulation.

High-flow oxygen and hyperbaric oxygen: The half-life of CO for a patient who is breathing room air is about 250–320 minutes, for a patient breathing high-flow oxygen via a nonrebreathing face mask is about 90 minutes, and with 100% HBO is about 30 minutes. The indications for HBO are as follows:

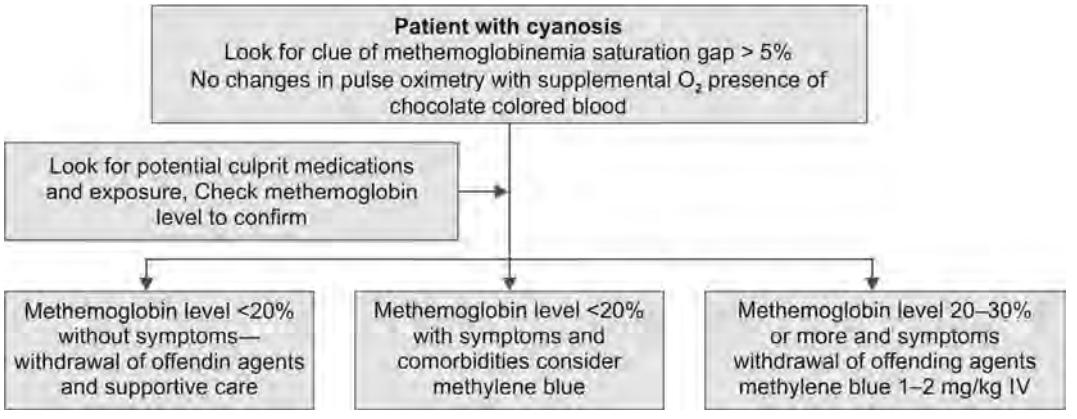
- CO level >25%
- CO level >20% in a pregnant patient
- Loss of consciousness or low Glasgow Coma Scale (GCS)
- Severe metabolic acidosis (pH <7.1)
- Evidence of end-organ damage (e.g., ECG changes, chest pain, or altered mental status)

Hyperbaric oxygen treatment involves exposing patients to 100% O_2 under supra-atmospheric conditions. This leads to a reduction in the half-life of CO-Hb, from about 90 minutes on 100% normobaric oxygen to about 30 minutes during HBO. The amount of oxygen dissolved in the blood also rises from around 0.3–6.0 mL/dL, which substantially increases the release of non-hemoglobin-bound O_2 to the tissues. HBO treatment may be beneficial in preventing the late neurocognitive deficits associated with severe CO toxicity.

Comatose patients, or those with low GCS, should be intubated and mechanically ventilated using 100% oxygen. In smoke inhalation patients (who may suffer from both cyanide and CO poisoning), hydroxocobalamins should be given. The dose of hydroxocobalamin is 70 mg/kg given intravenously (IV).

SUMMARY

Hemoglobin can bind gases other than oxygen, these include carbon monoxide nitrous oxide. Normal hemoglobin can be oxidized to methemoglobin and sulfhemoglobin by exogenous agents or can be found as a result of germline mutations. these modified hemoglobin referred as dyshemoglobinemia. Methemoglobinemia form when iron of the heme group oxidized and converted to ferrous to ferric group. The ferric heme of methemoglobin unable to bind reversely to oxygen. Acquired methemoglobinemia can arise from exposure to many commonly encountered compounds. As methemoglobin levels rise, serious symptoms can develop. Prompt recognition of methemoglobinemia is crucial and may be aided by clinical features that are unique to methemoglobinemia, such as a saturation gap. Management includes the withdrawal of offending medications and methylene blue in certain patients. Treatment with methylene blue should be considered in patients with significant symptoms, elevated methemoglobin levels, or comorbid conditions that compromise oxygen delivery (**Flowchart 1**). Carboxyhemoglobin is related to fire related smoke and The diagnosis of CO poisoning is based upon high carboxyhemoglobin level measured by co-oximetry of an arterial blood gas (ABG) sample. Management consists of high-flow oxygen via a nonrebreathing face mask and hyperbaric oxygen therapy.



Patient with cyanosis
Look for clue of methemoglobinemia saturation gap > 5%
No changes in pulse oximetry with supplemental O2 presence of chocolate colored blood
Look for potential culprit medications and exposure, Check methemoglobin level to confirm
Methemoglobin level <20% without symptoms—withdrawal of offendin agents and supportive care
Methemoglobin level <20% with symptoms and comorbidities consider methylene blue
Methemoglobin level 20–30% or more and symptoms withdrawal of offending agents methylene blue 1–2 mg/kg IV

FLOWCHART 1: Summary treatment of methemoglobinemia.

215
CHAPTER

Toxic Plants

TV Ramakrishnan, Mona Lisa

INTRODUCTION

The incidence of poisoning in India is among the highest in the world, and it is estimated that more than 50,000 people die every year from toxic exposure. The incidence of plant poisoning is around 1.7% of the total poisoning cases. There are a wide variety of toxicities caused by poisonous plants (**Box 1**). This chapter enlightens on the most common plant poisons, their toxic components, symptomatic approach, and management.

THEVETIA PERUVIANA

Synonym: Yellow oleander. It is an ornamental plant belonging to the *Apocynaceae* family (**Fig. 1**). Ingestion of plant parts causes digoxin-like toxicity, affecting cardiac myocytes. Toxic cardiac glycosides of almost eight different types include mainly *thevetin A, thevetin B,* and *neerifolin*. All parts are dangerous, especially the seeds. The toxic dose is ingestion of 8–10 seeds or 5–10 leaves.

Mechanism of Action

Inhibition of the transmembrane $3Na^+/2K^+$ ATPase pump increases intracellular concentrations of Ca^{2+} and Na^+ which cause arrhythmogenic effects on the heart.

BOX 1: Common plant poison in India.

- *Thevetia peruviana*
- *Nerium odorum*
- *Datura metel*
- *Abrus precatorius*
- *Myristica fragrans*
- *Nicotiana tabacum*
- *Strychnos nux-vomica*
- *Gloriosa superba*
- *Ricinus communis*
- *Calotropis*
- *Cannabis sativa*
- *Cleistanthus collinus*

Symptoms

Immediately after consumption, it causes a burning sensation in the mouth, dry throat, nausea, vomiting, and diarrhea. Cardiac manifestations are the major features seen, varying from bradyarrhythmias to tachyarrhythmias. It also causes anxiety, convulsions, and coma.

Specific Investigations

- *ECG*: To identify cardiac conduction defects.
- *Serum electrolytes*: Hypokalemia and hypomagnesemia worsen the toxicity and hyperkalemia is life-threatening.

Treatment

Thevetia peruviana poisoning can be treated by gastric decontamination using activated charcoal, if the patient presents early to the emergency department (ED). Arrhythmia should be managed based on the type identified. Atropine for bradyarrhythmia and lidocaine for tachyarrhythmia are preferred. Administration of digoxin-specific antibody fragments is indicated, if serum potassium >5 mEq/L after an acute overdose or in any cardiac dysrhythmia.

FIG. 1: *Thevetia peruviana* (yellow oleander). ***(For color version, see plate 37)***

Courtesy: Avighna Richhariya.

NERIUM ODORUM

Synonym: Pink oleander. It belongs to the same family as yellow oleander with a similar mechanism of action and contain the cardiac glycosides, *oleandrin* and *neriine* (**Fig. 2**). Both have positive inotropic, negative chronotropic, and cross-reactivity. All parts of the plant are toxic, which cause gastrointestinal effects such as nausea, vomiting to cramping, and bloody diarrhea. Confusion, dizziness, drowsiness, weakness, visual disturbances, and mydriasis are central nervous system (CNS) manifestations. Treatment remains the same as for yellow oleander.

DATURA METEL

Synonym: Indian thornapple, Devil's trumpet. It is a hallucinogenic plant with ornamental and medicinal properties, belonging to the *Solanaceae* family (**Fig. 3**). All parts of the plant are poisonous due to the higher contents of *tropane alkaloids* (especially seeds and fruit). The lethal dose is 0.6–1 g.

FIG. 2: *Nerium odorum* (pink oleander). ***(For color version, see plate 37)***

Courtesy: Avighna Richhariya.

Mechanism of Action

Tropane alkaloids, such as *Atropine, hyoscine,* and hyoscyamine, are the competitive antagonist of central and peripheral acetylcholine receptors. They cause general paralysis of all parasympathetic innervated organs (*anticholinergic syndrome*).

Symptoms

The features are similar to atropine toxicity. Dry skin and mucosa, flushing, mydriasis, tachycardia, hyperpyrexia, decreased bowel activity, and urinary retention are some of the symptoms. CNS manifestations are ataxia, psychosis, confusion, hallucinations, seizures, and coma. Acute kidney injury is a frequent finding (10–50%), due to direct toxicity and secondary myoglobinuria.

Treatment

Gastric decontamination can be done and benzodiazepines are used to sedate an agitated patient. Hyperpyrexia is treated with fluid administration and external cooling methods. In severe cases, physostigmine (cholinesterase inhibitor) is given intravenously (IV) in a dose of 0.5–2.0 mg at a rate of not >1 mg/min. A second dose is given if indicated.

ABRUS PRECATORIUS

Synonyms: Rosary pea, Jequirity bean, Love bean. It is a poisonous, flowering plant belonging to the *Fabaceae* family (**Fig. 4**). The toxic part is the seed; even one crushed seed can be fatal due to the release of *abrin* toxalbumin. The seed when ingested intact passes out undigested. The lethal dose is —one to two seeds.

Mechanism of Action (*Abrus Precatorius* and *Ricinus Communis*)

Ricinus and *Abrus* are differ somewhat in appearance and taxonomy but contain toxins (toxalbumin) that are structurally and functionally similar. Toxalbumins are proteins that bind

FIG. 3: *Datura metel*.

Courtesy: Avighna Richhariya.

FIG. 4: *Abrus precatorius*.

to carbohydrates. Molecular structure of both compounds *Ricin* and *Abrin* are similar, consist of two peptide chains that are cross-linked by two bisulfide bonds. The B chain, or "haptomer," binds to galactose containing receptors on the cell surface. The A chain, or "effectomer," then penetrates the cell and is transported into the cytoplasm to the ribosomes where it interrupts protein synthesis. B chain facilitates entry of A chain into cells and A chain prevents protein synthesis and causes cell death.

Symptoms

Ingestion can cause nausea, severe vomiting, abdominal pain, and bloody diarrhea (classical feature). It can be fatal due to severe dehydration and electrolyte abnormalities. Symptoms can be delayed for 1–3 days after ingestion and the clinical course can last for 10 days. The rare complications are encephalopathy, arrhythmias, and renal failure.[13]

Treatment

No specific antidote is available for *Abrin* poisoning. Treatment is mainly supportive with fluids and correction of electrolyte abnormalities.

MYRISTICA FRAGRANS

Synonyms: Nutmeg, Mace tree. It is an evergreen tree belonging to the *Myristicaceae* family. It is a source of spices (nutmeg and mace). It has psychotropic effects due to the release of *myristicin* and *elemicin.* The lethal dose is ingestion of one to three nutmegs.

Mechanism of Action

Myristicin metabolizes into 3-methoxymethylenedioxyamphetamine which has sympathomimetic action, hallucinogenic effects, and also serotonin agonist which exerts cardiac effects.

Symptoms

It causes varied manifestations, including nausea and vomiting. Cardiac manifestations include tachycardia and hypertension. CNS features are hallucinations, agitation, drowsiness, vertigo, confusion, seizures, and urinary retention (anticholinergic effect). Respiratory depression leads to death.

Treatment

Treatment is symptomatic and supportive. Gastric lavage is done if the patient presents within a couple of hours after ingestion. Sedatives are given to calm the patient and anticonvulsants in case of seizures.

NICOTIANA TABACUM

Synonym: Tobacco. It is a herbaceous plant of the *Solanaceae* family (**Fig. 5**). Every part of the plant, except the seeds, contains the poisonous *nicotine*. Leaves, along with nicotine, also contain *citrate* and *malate.* About 64% of nicotine is seen in leaves and the concentration increases with the age of the plant. The lethal dose is 60–100-mg nicotine or 2-g tobacco. The poisonous *pyridine alkaloids* present apart from *nicotine*

FIG. 5: *Nicotiana tabacum*.

(90–95%) are *nornicotine* and *anatabine*. The methods of entry include oral ingestion, inhalation, and percutaneous absorption.

Mechanism of Action

Nicotine causes stimulation of preganglionic nicotinic acetylcholine receptors of the autonomic nervous system which in turn causes cardiovascular and CNS effects.

Symptoms

The onset of symptoms in acute poisoning is usually rapid. In severe poisoning of the alkaloid, the patient may collapse and die within minutes. The gastrointestinal symptoms include salivation, nausea, vomiting, and diarrhea. Cardiovascular manifestations include hypertension (initially followed by hypotension in later stages), tachycardia, arrhythmias, and labored breathing. Parasympathetic stimulation of CNS leads to mental confusion, giddiness, restlessness, muscle weakness, disturbed vision, seizures, and unconsciousness. Death usually occurs due to complete paralysis and respiratory arrest.

Diagnosis

Diagnosis is based on history and clinical findings. Sample collection for toxic screening is indicated.

Treatment

Stomach wash is indicated for oral ingestion. There is no specific antidote. Convulsions are controlled with benzodiazepines while ensuring that airway patency and respiration are maintained.

STRYCHNOS NUX-VOMICA

Synonyms: Strychnine tree, Poison nut. It is a deciduous tree belonging to the *Loganiaceae* family. It is highly poisonous due to the presence of alkaloids—*strychnine, loganin,* and *brucine* in the seeds, leaves, and tree bark. The possible ways of poisoning are oral ingestion, inhalational, transdermal, and intravenous toxin. The lethal dose is 30–120 mg (1–2 mg/kg).

Mechanism of Action

Strychnine competitively inhibits glycine receptors in the spinal cord (glycine—inhibitory neurotransmitter) which in turn causes uncontrolled stimulation of postsynaptic neurons and involuntary muscle contractions (*awake seizures*).

Symptoms

Symptoms appear fast, within 15–30 minutes of exposure. The initial signs of poisoning include nervousness, restlessness, twitching of the muscles, neck stiffness, and tetanic convulsions of all striated muscles. Convulsions last from 30 seconds to 2 minutes and are more pronounced in the antigravity muscles causing *opisthotonos*. *Risus sardonicus* due to contractions of facial muscles giving a sardonic smile is a classical feature. Tachycardia, hyperthermia, and airway compromise from the stiffness of neck are other features. Rhabdomyolysis, hyperkalemia, lactic acidosis, metabolic acidosis, and kidney failure are later features. Death usually occurs due to respiratory compromise.

Evaluation

Blood assays include arterial or venous blood gas, lactates, serum electrolyte, and urine analysis for detection of rhabdomyolysis.

Treatment

Early intubation is advised. Succinylcholine must be avoided due to the risk of hyperkalemia. Gastric lavage is indicated if presenting early. Benzodiazepines or barbiturates are used to control muscle contractions.

GLORIOSA SUPERBA

Synonyms: Climbing lily, Creeping lily, Glory lily, *Gloriosa* lily, Tiger claw, and Fire lily. It is a flowering plant belonging to the *Colchicaceae* family. Every part of the plant is highly poisonous, especially the tubers. Its toxicity is due to antimitotic effects of the alkaloids, *colchicine* and *gloriosine*, on rapidly proliferating cells. The lethal dose is about 60 mg in adults and the fatal period is 12–72 hours.

Colchicine arrests mitosis in metaphase cell death.

Symptoms

The common clinical presentation in acute poisoning is gastroenteritis; it also causes nausea, burning and tingling oral cavity, bloody diarrhea leading to hypovolemic shock, and renal failure. Other features include delirium, convulsions, acute respiratory distress syndrome, coagulopathy, multiorgan failure, ascending polyneuropathy, and cardiotoxicity with ST-elevation occurring within 12–36 hours. Generalized alopecia is also a recognized feature.

Treatment

Symptomatic treatment is given with stomach wash. Secure airway and maintain ventilation; administer a lot of IV fluids in case of hypovolemia to correct electrolyte imbalance. Maintain urine output; overt renal failure may require hemodialysis. Hemorrhagic complications require transfusion of blood products.

RICINUS COMMUNIS

Synonym: Castor oil plant. It is a flowering plant belonging to the *Euphorbiaceae* family (**Fig. 6**). Toxicity is caused by ingestion of seeds containing highly toxic protein *ricin* (toxalbumin) and less toxic alkaloid *ricinine*. Seeds are toxic only if the outer shell is broken or chewed. The lethal dose is 1–20 mg/kg. Routes of exposure are inhalation, ingestion, and intravenous.

Symptoms

Inhalation causes cough, fever, chest tightness, dyspnea, and distress leading to pulmonary edema. Ingestion causes nausea, vomiting, diarrhea, and abdomen pain. It can cause miosis or mydriasis. CNS manifestations are vertigo, delirium, convulsions, and coma.

Treatment

No specific antidote is available for ricin. Gastrointestinal decontamination using activated charcoal can be done. Treatment is supportive and symptomatic.

CALOTROPIS

Synonym: Milkweed. It is a flowering plant of the *Apocynaceae* family. The milky exudate from stems and leaves is corrosive poisoning. The chemical components from the latex are *calotropin, calotoxin, calactin*, *uscharin,* and *gigantin*. They were used as an arrow poison. Exposure irritates the eye and oral mucosa, cardiotoxicity, and neurotoxicity. Due to anticholinergic responses, it can cause various fatal presentations. The lethal dose is 0.12 mg/kg calotropin. The fatal period varies from 30 minutes to 8 hours.

Symptoms

Ocular exposure causes various effects due to corneal edema. It manifests immediately with irritation, pain, and photophobia.

FIG. 6: *Ricinus communis* (castor oil plant).

After a few hours, it causes painless diminution of vision, toxic iridocyclitis, and secondary glaucoma. On ingestion, it causes burning pain in the throat and abdomen, salivation, vomiting, diarrhea, mydriasis, delirium, tremors, tetanic convulsions, and death.

Treatment

Management remains supportive care with gastric lavage, oxygen administration, and airway protection. Copious irrigation is needed in case of exposure to the eyes and further ophthalmological evaluation.

CANNABIS SATIVA

Synonyms: Indian hemp, Hashish. It belongs to the *Cannabaceae* family. *Marijuana* is tobacco-like preparation from the leaves and flowers of the plant. It is mainly used for recreational purpose and it contains various compounds and cannabinoids; it is important if *tetrahydrocannabinol* (THC). Acute effects depend on the dose and route of exposure (inhalational, ingestion). Approximately 2–3 mg of inhaled and 5–20 mg of ingested THC is enough to cause psychotropic effects. Severe effects are seen with a dose of >7.5 mg/m^2 THC.

Mechanism of Action

Cannabis act by cannabinoid receptors (CB1 and CB2). CB1 in the CNS inhibits the release of gamma-aminobutyric acid (GABA), dopamine, acetylcholine, 5-hydroxytryptamine, and norepinephrine. CB2 receptors act on peripheral nerve terminals.

Symptoms

It presents with conjunctival redness, dry mouth, nystagmus, hyperemesis, and abdominal pain. CNS effects are ataxia, incoordination, impaired judgment, sedation, CNS depression, and coma (more common in children). Psychiatric manifestations include euphoria and relaxation, agitation, anxiety, time disorientation, hallucinations, delusions, and acute psychosis. Tachycardia, orthostatic hypotension or elevated blood pressure, and tachypnea are other signs.

Evaluation

Standard urine drug screen can be used to detect THC carboxylase. ECG and cardiac markers should be done in case of chest pain, to rule out infarction. Always consider co-ingestion.

Treatment

Treatment is supportive and to maintain airway, breathing, and circulation. Benzodiazepines are used in case of agitation or seizures.

CLEISTANTHUS COLLINUS

This is a toxic shrub of the *Phyllanthaceae* family. All parts of the plant are toxic. Ingestion of leaves is more common. The toxic substances are *cleistanthin A, cleistanthin B*, and *collinusin* and *diphyllin*. Cleistanthin inhibits deoxyribonucleic acid (DNA) synthesis and cell division.Cleistanthin B induces chromosomal aberrations.

Symptoms

It presents commonly with gastrointestinal symptoms such as vomiting, abdominal pain, diarrhea, dysphagia, salivation, and abdominal distension. Chest pain, dyspnea, tachycardia or bradycardia, hypotension, and cyanosis are the cardiac symptoms. Neurological features are muscle cramps and weakness, altered sensorium, giddiness, headache, and tremors. Laboratory findings show hypokalemia with metabolic acidosis, elevated hepatic transaminases, hyponatremia, and coagulopathy. Fatal complications are renal failure, respiratory distress, and shock.

Treatment

Treatment is supportive care, gastric decontamination with activated charcoal if the patient presents early. N-acetylcysteine has been suggested as a possible antidote for management.

SUMMARY

Most of the patients presented with mild toxicity after toxic plant ingestion to the ED. Serious toxicity only occurs if taken deliberately in a large amount or taken mistakenly as edible plants. Identification of plants is an important part and management is generally supportive except for those who have cardiac glycosides and present with cholinergic and anticholinergic symptoms. Plant toxins are summarized in **Table 1**.

TABLE 1: Summary of toxic plants.

Toxic plant	*Toxic part*	*Toxic component*	*Lethal dose*
Thevetia peruviana	All parts	Thevetin A, thevetin B, and neriifolin	8–10 seeds or 5–10 leaves
Nerium odorum	All parts	Oleandrin, nerine	
Datura metel	All parts	Tropane alkaloids—atropine, hyoscine, and hyoscyamine	0.6–1 g
Abrus precatorius	Seeds	Abrin toxalbumin	1–2 seeds
Myristica fragrans	Seeds	Myristicin, elemicin	1–3 nutmegs
Nicotiana tabacum	All parts except seeds	Nicotine, nornicotine, and anatabine	60–100-mg nicotine or 2-g tobacco

Continued

Continued

Toxic plant	*Toxic part*	*Toxic component*	*Lethal dose*
Strychnos nux-vomica	All parts	Strychnine, loganin, and brucine	30–120 mg (1–2 mg/kg)
Gloriosa superba	All parts	Colchicine, gloriosine	60 mg in adults
Ricinus communis	All parts (mainly seeds)	Ricin, ricinine	1–20 mg/kg
Calotropis	Exudate, roots	Calotropin, calotoxin, calactin, uscharin, and gigantin	0.12 mg/kg calotropin
Cannabis sativa	Almost all parts	Tetrahydrocannabinol (THC)	>7.5 mg/m^2 THC
Cleistanthus collinus	All parts (leaves mainly)	Cleistanthin A, cleistanthin B, and dyphylline	–

216
CHAPTER

Pediatric Toxicology

Nisreen Hamza Maghraby, Chafika Lasfer, Mohamad Al Jumaan

INTRODUCTION

Poisoning in pediatrics is a common emergency, mostly unintentional because children are curious by nature about the many household products and medications available to them at home. They will be brought in by anxious parents who may or may not have accurate information regarding suspicion of exposure. Failure to consider the major differences in pediatric toxicology as well as concerning historical and examination features may lead to a delay in detection or treatment of these cases. Fortunately, fatalities are rare, and most young patients ingest substances that are minimally toxic or nontoxic and in smaller quantities than is seen with adolescents and adults. A 2018 annual report of the American Association of Poison Control Centers found that children <5 years of age accounted for 44.2% of exposures, cosmetic analgesics and household cleaning agents being the most common toxins (**Fig. 1**). Other common substances which are exposed to a child are toys, topical preparations, pesticides, antimicrobials plants vitamins, antihistamines, and cough syrups. This chapter is concerned with highlighting the major concerns when managing a pediatric poisoned patient. It provides a clear clinical approach to a suspected poisoned child.

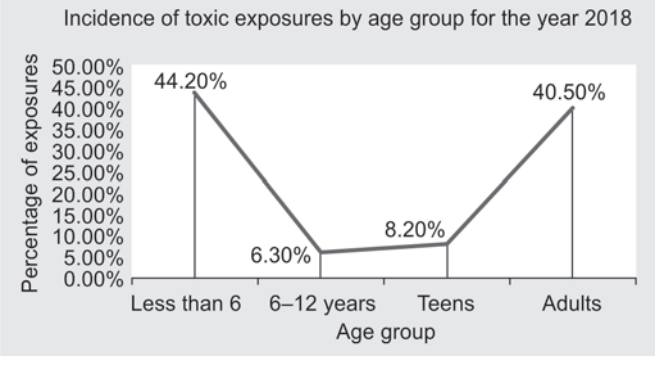

FIG. 1: Incidence of toxic exposures by age group for the year 2018.

PHARMACOKINETIC DIFFERENCES IN PEDIATRIC AGE

The maxim "children are not just small adults" is most valid when we consider the following key pharmacokinetic factors (**Table 1**) that influence the effects of drugs and toxins on a child. It is important to note that these processes are dynamic and continue to develop in children as they age and that they begin to resemble those of the adult population near adolescence.

EMERGENCY EVALUATION

Initial Stabalization and Life Support Measures

The emergency evaluation of the poisoned child begins with the same approach of "airway, breathing, circulation" to identify the patients in need of resuscitation and immediate life-supporting measures. In the context of toxicology, however, the primary survey is also extended to include the following: *Disability, drugs (emergency antidotes), and decontamination.* Other measures include obtaining an *ECG* and management of *fever (hyperthermia)* if present. This approach prioritizes stability of the child over obtaining a complete history and physical examination. For patients who present with signs of instability or shock, the following actions should be rapidly undertaken: Complete set of vital signs should be recorded, intravenous/intraosseous (IV/IO) access obtained with blood drawn for investigations, continuous cardiac monitoring initiated with the placement of pads, bedside glucose measurement, preparation of equipment, and medication according to the patient's weight and age.

Airway: *Ensuring* a patent airway is the first step in stabilization and the threshold for intubating an unstable poisoned child is relatively low, as these patients do not tolerate hypoxia well and will desaturate quickly.

Airway should be protected by intubation in cases of risk of aspiration, e.g., depressed mental state, loss of protective

TABLE 1: Pharmacokinetic factors in the pediatric population.

	Key differences	*Clinical implications*
Absorption	• Smaller gastrointestinal surface area with limited intestinal absorption • Delayed gastric emptying • Thinner skin, higher body surface area • Increased minute ventilation and respiratory rate	• Absorption via nonoral routes can be erratic • Weakly acidic drugs may need higher dosing • Higher toxicity seen with topically applied medicine • Children more susceptible to inhaled toxins such as carbon monoxide
Distribution	• Higher volume of water • Less fat content • Less protein binding • Higher blood–brain barrier permeability	Ceftriaxone is contraindicated in infants younger than 28 days and displaces bilirubin from albumin, leading to kernicterus
Metabolism	• Higher metabolic rate in children • Immature liver enzymes in infants	• Benzyl alcohol is toxic to children at much lower doses than in adults, leading to neonatal gasping syndrome and potential death • Carbamazepine requires higher dosing in children compared to adults
Elimination	• Predominant renal clearance • Decreased glomerular filtration rate • Decreased renal tubular reabsorption	Renally excreted drugs require lower or less frequent dosing regimens to avoid toxicity

airway reflexes oropharyngeal injuries due to caustic ingestion or anticipating deterioration in case of witnessed ingestion of lethal doses of tricyclic antidepressant.

Breathing: The respiratory rate and character of breathing should be noted. Attention should be paid to correlate the rate of breaths with the patient's age and to look for signs of increased work of breathing (nasal flaring, suprasternal or subcostal retractions). Continuous pulse oximetry should be initiated as well. However, this should not delay interventions at the bedside and the physician may rely on clinical judgment to begin ventilatory support.

Supplemental oxygen should be initiated and titrated to a saturation of >94%. One exception is the ingestion of *paraquat*, a corrosive herbicide that can be lethal to children in very small doses. When paraquat poisoning is suspected, supplemental oxygen should be withheld unless saturation is below 90% as free oxygen radicals can cause cellular injury.

If a patient with severe acidemia is intubated, respiratory compensation should be maintained to prevent decompensation. Therefore, a ventilator strategy that allows hyperventilation of the child should be initiated to prevent worsening acidemia.

Circulation: Owing to physiologic differences, cardiac output in children is dependent on changes in heart rate rather than stroke volume. As such, if a pediatric patient is in a state of shock, this may only be subtly evident through a compensatory increase in heart rate. Ingestion of cardiovascular drugs, such as calcium channel blockers, that block this compensatory mechanism is especially dangerous in children. Furthermore, if tachycardia is not addressed in a timely manner, the patient might deteriorate further with evidence of hypotension, which is a late sign. Other signs of shock that should be sought include a delayed capillary refill >2 seconds, skin mottling, and faint pulses. If bradycardia is found, efforts to prevent impending cardiac arrest are necessary by securing IV access early in the resuscitation phase. Assess for signs of shock. Administering fluid boluses at 20 mL/kg up to a total of 60 mL/kg is titrated to clinical effect. Initiation of vasopressors may be necessary.

Disability: When assessing a child's mental status, using the AVPU (Alert-Verbal-Pain-Unresponsive) scale is a faster and more convenient method compared to the Glasgow Coma Scale (GCS). Scores of A, V, P, and U correspond to GCS scores of 15, 13, 8, and 3, respectively. Pupils' size and reactivity should be noted, along with the presence of any nystagmus. A bedside glucose measurement should be obtained quickly upon arrival of the patient as hypoglycemia is common in this age group and may mimic other causes of altered mental status. Any seizure activity should be treated immediately.

Decontamination: As described above, children are more susceptible to toxicity through skin exposure than adults. The patient should be fully exposed with the removal of any contaminated clothes and washing of the skin with water. Care should be taken not to accidentally induce hypothermia and the patient should be covered with blankets. If the eyes are exposed to chemicals, ocular irrigation with normal saline should be started.

Gastrointestinal decontamination with activated charcoal may be considered if patients present immediately after a toxic ingestion of a substance known to adsorb to charcoal. The greatest benefit is seen if it is given within 1 hour of ingestion; however, it may be considered if the patient has taken substances known to delay gastric emptying. Furthermore, if antidotal therapy is subsequently delivered, its absorption may be impaired due to the administration of activated charcoal. In any case, the benefit of activated charcoal administration must outweigh the potential risk of aspiration in an obtunded child whose airway is not secure. In awake and cooperative children, mixing activated charcoal with ice-cream or soda may improve its taste. The dose is 1–2 g/kg.

TABLE 2: Emergency antidotes.

Antidote	*Indication*
Oxygen	Hypoxemia
Naloxone	Opioid-induced respiratory depression
Benzodiazepines	First-line treatment of toxic seizures, agitation
Dextrose	Hypoglycemia
Sodium bicarbonate	Cardiotoxicity due to sodium channel-blocking agents (wide QRS on ECG), tricyclic antidepressant
N-acetylcysteine	Acetaminophen
Flumazenil	Benzodiazepine
Glucagon	β-blockers
Calcium, glucose + insulin lipid emulsion	Calcium channel blocker
Ethanol, fomepizole	Methanol
Methylene blue	Methemoglobinemia
Vitamin K	Coumadin (another similar rodenticide)
Deferoxamine	Iron
Pyridoxine	Isoniazid
Atropine and pralidoxime	Organophosphorus insecticides

Drugs—antidotes: During resuscitation, few emergency antidotes may be indicated in certain scenarios given in **Table 2**.

ECG: Obtain an ECG upon arrival of any patient suspected of poisoning. Changes in QRS width, QTc length, evidence of arrhythmias, heart blocks, or terminal R wave in aVR may point to specific toxicities.

Fever: Presence of fever should raise suspicion of life-threatening poisoning, as is seen with sympathomimetic and anticholinergic toxidromes. Core temperatures should be measured. Presence of fever above 39.5°C should be promptly treated. Initiation of active cooling measures. Intubation with paralysis will help to prevent further heat production. Hypothermia, on the other hand, can be associated with carbon monoxide, sedative-hypnotic, or alcohol toxicity and should be corrected.

HISTORY AND PHYSICAL EXAMINATION

History

As an important step in forming the individualized risk assessment, the history is primarily concerned with answering these following questions: *"What, How, How much, When, and Why"*.

When obtaining history regarding a possible ingestion in a young patient, few challenges may arise. First, most ingestions occur in children too young to be reliable historians. Second, the event of ingestion may have been unwitnessed by caregivers at home. Therefore, a high index of suspicion should be maintained not to miss pediatric poisoning. Whenever in doubt of a clear history, "worst-case scenarios" should be believed. Past medical history should be obtained to detect populations more susceptible to toxicity; e.g., mothball toxicity is more severe in a patient known to have glucose-6-phosphate dehydrogenase deficiency.

Identifying *what* the poison is, *how* it was taken, and *how much* of it was taken: This includes recognizing the substance of poisoning and its route. Although children can also be poisoned by inhalation and dermal contact, ingestion is the most common route. Iatrogenic poisoning is another cause of toxicity, as all medications are weight-based and medication errors may occur. Asking about all available medications at home with their specific formulations is important. Fortunately, most children will ingest medications in small quantities.

However, it is important to obtain the exact dose ingested per weight of any child to determine the level of risk posed to his/her health. *Worst-case scenario*: Assume that the patient has taken the largest dose available to him/her at the time of ingestion. If more than one child is present, assume that all have taken the same maximum dose. For example: If three children were brought by parents who found an empty 30-pill bottle of medicine, assume that all three have ingested all 30 pills. In toddlers, if the ingested pill is unknown, assume it to be one that can kill in small doses, until proven otherwise.

One Pill Can Kill: It is also worth mentioning that certain drugs can induce severe toxicity in the pediatric population if taken in small doses. Known collectively as the *"one pill can kill"* group, they include antimalarials, beta-blockers, calcium channel blockers, camphor, clonidine, tricyclic antidepressants, sulfonylureas, salicylates, and toxic alcohols, to name a few. *A summary of these drugs, the fatal dose, highest dose available, mechanism of toxicity, and signs/symptoms is provided in* **Table 3**.

Identifying the *when* of ingestions: As most of these ingestions occur unwitnessed, it is often difficult to know exactly when ingestions took place. This is important, however, as some medications have delayed onset of symptoms. Prolonged observation time in all pediatric poisoning is warranted as well, owing to their different pharmacokinetics. *Worst-case scenario*: Assume the latest possible time of ingestion. The exception to this is paracetamol, where the earliest ingestion time is assumed. In toddlers, if the time of ingestion is unknown, keep patients for 12-hour observation periods and watch for onset of symptoms.

Identifying the *why* of ingestions: Asking about the circumstances of possible poisoning aims to identify red flags that may raise suspicion of neglect, abuse, or intentional ingestions. Most of the reported poisoning cases between the ages of 1 and 5 years occur unintentionally as children in this age group are more likely to explore their surroundings or mistake medications and substances for candy. Older children and adolescents are less likely to have accidental ingestions, and a history of substance abuse and suicidality should be sought. Other factors that can contribute to poisoning are the arrival of a new baby, moving homes, parental illness, and grandparent's caretaking.

Worst-case scenario: Historical "Red Flags": Suspect neglect or abuse if history is inconsistent with the presentation, if there is

TABLE 3: Summary "one pill can kill."

Drug	*Potentially fatal dose (mg/kg)*	*Highest dose available (mg)*	*Mechanism of toxicity*	*Signs/Symptoms of toxicity*
Calcium channel blocker	15	360	Myocardial suppression	PR prolongation, bradydysrhythmias, hypotension, CHF
Tricyclic antidepressants	15	150	Na channel blockade, alpha 1 blockade	Coma, seizures, tachycardia followed by hypotension and bradydysrhythmias
Antimalarials	20	500	Na channel blockade, direct retinal damage	Prolonged QRS/QT, torsades, hypotension, tinnitus, vision loss, headache, vertigo, seizures
Opiates: Codeine	10	60	Respiratory depression	Miosis, CNS depression, hypopnea
Sulfonylureas	0.1	10	Activates insulin release	Hypoglycemia, irritability, lethargy, seizures, and coma
Class 1 antiarrhythmics	25	1	Na channel blockade	Prolonged PR/QRS, QT (class 1A agents), headache, nausea/vomiting
Camphor	50	550 mg/tsp	Unknown mechanism of neurotoxicity	Nausea, vomiting, agitation, myoclonus, hyperreflexia, intractable seizures
Oil of wintergreen (methyl salicylate)	400	7 g/tsp	Organic ester, crosses BBB and interferes with cellular metabolism	Mixed respiratory alkalosis/metabolic acidosis, vertigo, AMS, coma, pulmonary edema
Liquid nicotine	1–13	35 mg/mL	nAChR agonist at low doses, mAChR agonist at higher doses	Biphasic pattern: Hypertension, tachycardia, vomiting, followed by autonomic ganglionic blockade, hypotension, bradycardia, coma

(AMS: acute mountain sickness; BBB: blood–brain barrier; CHF: congestive heart failure; CNS: central nervous system)

Sources: Bar-Oz B, Levichek Z, Koren G. Medications that can be fatal for a toddler with one tablet or teaspoonful: a 2004 update. Pediatr Drugs. 2004;6(2):123-6; Davis JE. Are one or two dangerous? Methyl salicylate exposure in toddlers. J Emerg Med. 2007;32(1):63-9; Bassett RA, Osterhoudt K, Brabazon T. Nicotine poisoning in an infant. N Engl J Med. 2014;370:2249-50

a history of previous poisoning, if a massive overdose is present in a child younger than 1 year of age, if an illicit exposure is suspected, and if there are multiple siblings presenting at the same time. Suspect intentional ingestions in children above the age of 5 years and substance abuse in adolescents.

Physical Examination

Periodic reassessment of "ABCs" (airway, breathing, and circulation) and vitals during the observation period is essential. A focused examination will aim to detect any signs of toxicity as well as give clues toward certain toxidromes. As such examination is focused on central, autonomic nervous systems and cardiovascular and gastrointestinal systems. Examination of the skin may yield important clues to toxicity with the onset of jaundice, cyanosis, flushing, or discoloration.

INVESTIGATIONS

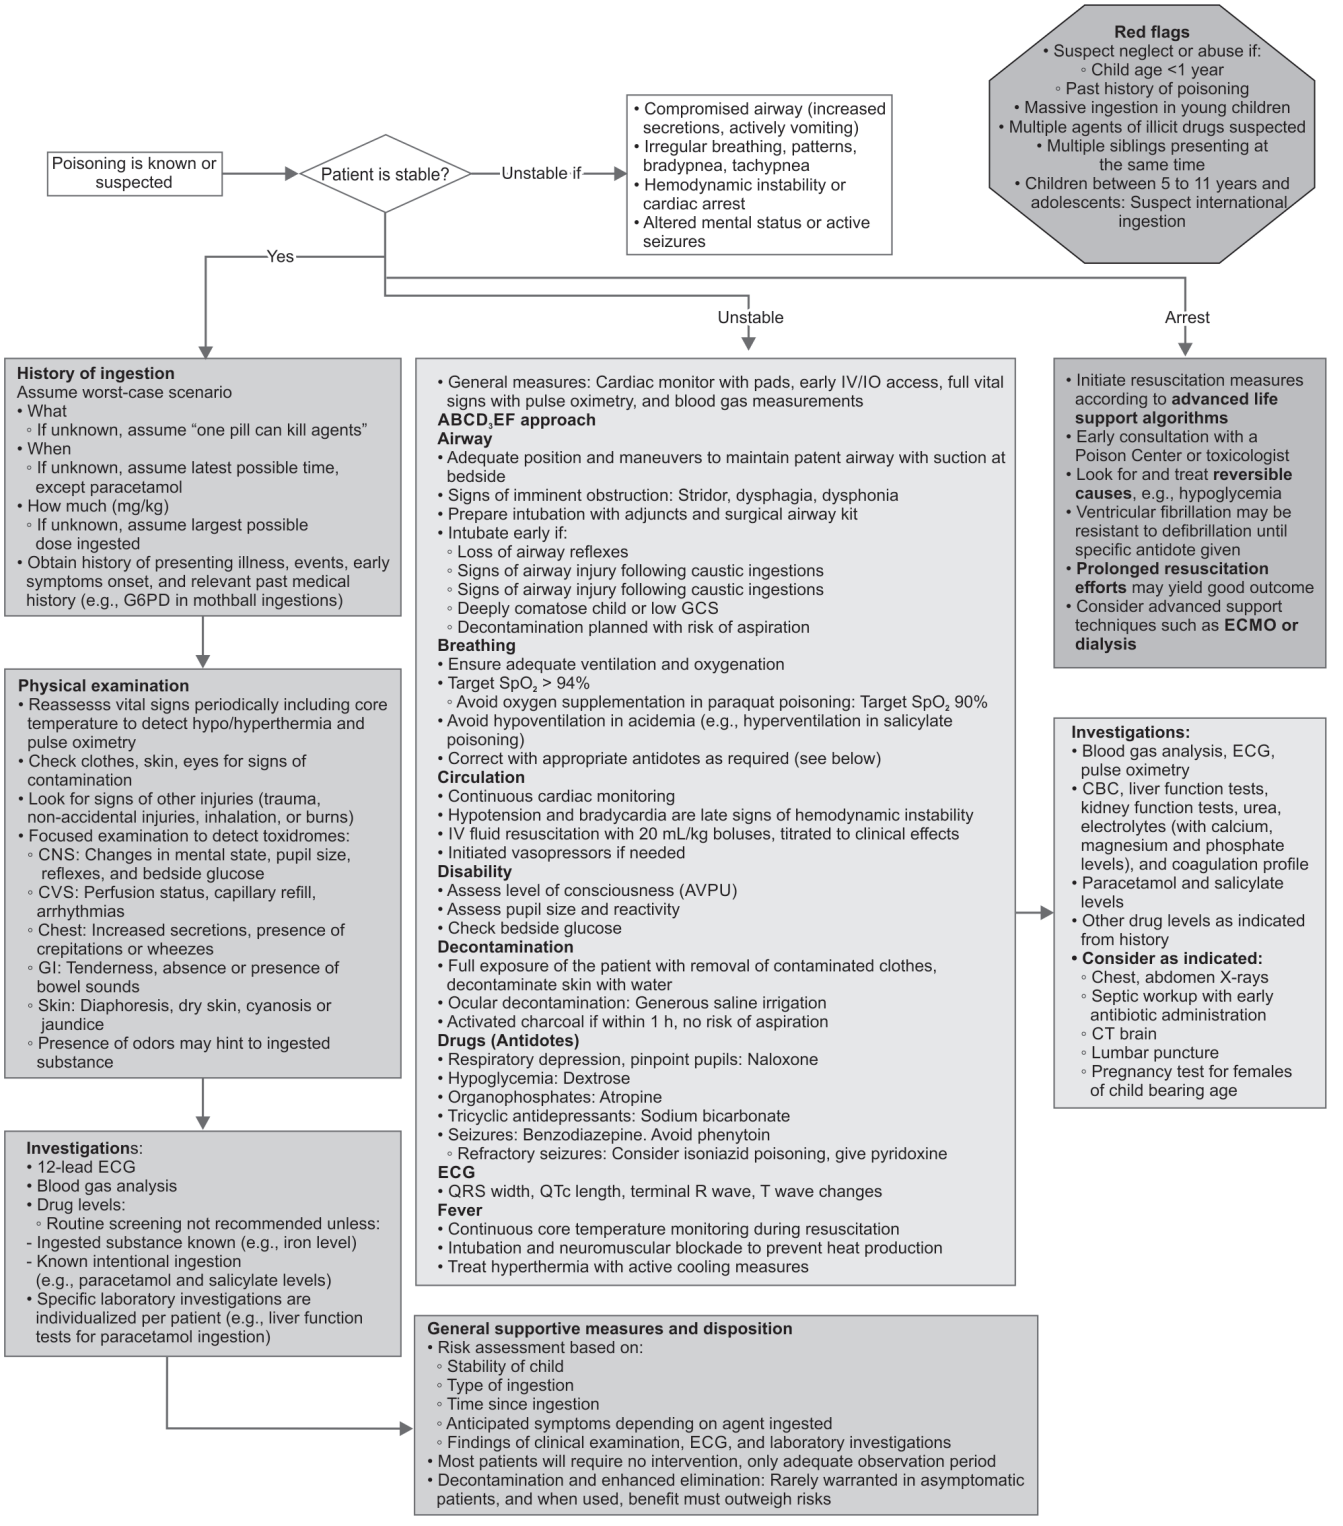
As most unintentional ingestions are asymptomatic and nontoxic, routine investigations and toxicology screens are not always warranted. Obtaining an ECG is a simple, rapid, noninvasive test that can detect signs of poisoning. Laboratory investigations are individualized to the need and clinical course of each patient. In the clinically poisoned child of unknown ingestion, a toxicology screen may be useful. If there is a suspicion of intentional ingestions then an ECG, a blood gas analysis, paracetamol, salicylate, and iron levels should be ordered. In the unstable child, a full workup is usually warranted, and this includes looking for other causes of instability such as infectious, surgical, and metabolic disorders.

MANAGEMENT

Management is usually dictated by the clinical presentation of the patient as well as by the risk assessment formulated by physicians. Most cases of pediatric poisoning are managed through close observation and supportive treatment. The time for observation depends not only on the type, time since, and quantity of ingestion but also on the age of the patient. Lower thresholds for admission and observation are maintained for toddlers with unknown ingestions. Emergency antidotes and decontamination are indicated in the unstable child as discussed above, and generally; most specific antidotal therapies follow the same principles as in adults. However, care should be taken to avoid dosing errors in children. **Flowchart 1** summarizes the emergency approach for managing the pediatric poisoning.

DISPOSITION

If the choice is made to discharge, parents must be educated regarding the dangers of accidental exposures. If neglect or abuse is suspected, then child protective services should be alerted according to local practice guidelines. A psychiatric assessment should be obtained for patients with intentional ingestions. In all cases, early consultation with a toxicologist or poison center will yield the best results.



Red flags
• Suspect neglect or abuse if:
◦ Child age <1 year
◦ Past history of poisoning
• Massive ingestion in young children
• Multiple agents of illicit drugs suspected
• Multiple siblings presenting at the same time
• Children between 5 to 11 years and adolescents: Suspect international ingestion
Poisoning is known or suspected
Patient is stable?
Unstable if
• Compromised airway (increased secretions, actively vomiting)
• Irregular breathing, patterns, bradypnea, tachypnea
• Hemodynamic instability or cardiac arrest
• Altered mental status or active seizures
Yes
Unstable
Arrest
History of ingestion
Assume worst-case scenario
• What
◦ If unknown, assume "one pill can kill agents"
• When
◦ If unknown, assume latest possible time, except paracetamol
• How much (mg/kg)
◦ If unknown, assume largest possible dose ingested
• Obtain history of presenting illness, events, early symptoms onset, and relevant past medical history (e.g., G6PD in mothball ingestions)
Physical examination
• Reassesss vital signs periodically including core temperature to detect hypo/hyperthermia and pulse oximetry
• Check clothes, skin, eyes for signs of contamination
• Look for signs of other injuries (trauma, non-accidental injuries, inhalation, or burns)
• Focused examination to detect toxidromes:
◦ CNS: Changes in mental state, pupil size, reflexes, and bedside glucose
◦ CVS: Perfusion status, capillary refill, arrhythmias
◦ Chest: Increased secretions, presence of crepitations or wheezes
◦ GI: Tenderness, absence or presence of bowel sounds
◦ Skin: Diaphoresis, dry skin, cyanosis or jaundice
◦ Presence of odors may hint to ingested substance
Investigations:
• 12-lead ECG
• Blood gas analysis
• Drug levels:
◦ Routine screening not recommended unless:
- Ingested substance known (e.g., iron level)
- Known intentional ingestion (e.g., paracetamol and salicylate levels)
• Specific laboratory investigations are individualized per patient (e.g., liver function tests for paracetamol ingestion)
• General measures: Cardiac monitor with pads, early IV/IO access, full vital signs with pulse oximetry, and blood gas measurements
ABCD$_s$EF approach
Airway
• Adequate position and maneuvers to maintain patent airway with suction at bedside
• Signs of imminent obstruction: Stridor, dysphagia, dysphonia
• Prepare intubation with adjuncts and surgical airway kit
• Intubate early if:
◦ Loss of airway reflexes
◦ Signs of airway injury following caustic ingestions
◦ Signs of airway injury following caustic ingestions
◦ Deeply comatose child or low GCS
◦ Decontamination planned with risk of aspiration
Breathing
• Ensure adequate ventilation and oxygenation
• Target SpO_2 > 94%
◦ Avoid oxygen supplementation in paraquat poisoning: Target SpO_2 90%
• Avoid hypoventilation in acidemia (e.g., hyperventilation in salicylate poisoning)
• Correct with appropriate antidotes as required (see below)
Circulation
• Continuous cardiac monitoring
• Hypotension and bradycardia are late signs of hemodynamic instability
• IV fluid resuscitation with 20 mL/kg boluses, titrated to clinical effects
• Initiated vasopressors if needed
Disability
• Assess level of consciousness (AVPU)
• Assess pupil size and reactivity
• Check bedside glucose
Decontamination
• Full exposure of the patient with removal of contaminated clothes, decontaminate skin with water
• Ocular decontamination: Generous saline irrigation
• Activated charcoal if within 1 h, no risk of aspiration
Drugs (Antidotes)
• Respiratory depression, pinpoint pupils: Naloxone
• Hypoglycemia: Dextrose
• Organophosphates: Atropine
• Tricyclic antidepressants: Sodium bicarbonate
• Seizures: Benzodiazepine. Avoid phenytoin
◦ Refractory seizures: Consider isoniazid poisoning, give pyridoxine
ECG
• QRS width, QTc length, terminal R wave, T wave changes
Fever
• Continuous core temperature monitoring during resuscitation
• Intubation and neuromuscular blockade to prevent heat production
• Treat hyperthermia with active cooling measures
• Initiate resuscitation measures according to advanced life support algorithms
• Early consultation with a Poison Center or toxicologist
• Look for and treat reversible causes, e.g., hypoglycemia
• Ventricular fibrillation may be resistant to defibrillation until specific antidote given
• Prolonged resuscitation efforts may yield good outcome
• Consider advanced support techniques such as ECMO or dialysis
Investigations:
• Blood gas analysis, ECG, pulse oximetry
• CBC, liver function tests, kidney function tests, urea, electrolytes (with calcium, magnesium and phosphate levels), and coagulation profile
• Paracetamol and salicylate levels
• Other drug levels as indicated from history
• Consider as indicated:
◦ Chest, abdomen X-rays
◦ Septic workup with early antibiotic administration
◦ CT brain
◦ Lumbar puncture
◦ Pregnancy test for females of child bearing age
General supportive measures and disposition
• Risk assessment based on:
◦ Stability of child
◦ Type of ingestion
◦ Time since ingestion
◦ Anticipated symptoms depending on agent ingested
◦ Findings of clinical examination, ECG, and laboratory investigations
• Most patients will require no intervention, only adequate observation period
• Decontamination and enhanced elimination: Rarely warranted in asymptomatic patients, and when used, benefit must outweigh risks

(CBC: complete blood count; CNS: central nervous system; CT: computed tomography; CVS: cardiovascular system; ECG: electrocardiogram; ECMO: extracorporeal membrane oxygenation; GCS: Glasgow Coma Scale; GI: gastrointestinal; G6PD: glucose-6-phosphate dehydrogenase; IO: intravenous; IV: intraosseous)

FLOWCHART 1: Clinical pathway for managing the pediatric poisoning.

SUMMARY

In the medical toxicology field, as compared to adult, children can present with various unique and complex problems to emergency department. Following the accidental toxic ingestions, fatalities in young children are rare however, some specific substances are extremely toxic to children even in small doses. It is necessary that the emergency physician be aware of these substances. Management of pediatric toxins need specialized approach because of its unique considerations

like the physiologic response to poisoning , evaluation and management, the impact on the child and family. Initial resuscitation and supportive care are the cornerstone of treatment in the poisoned child. Antidotes administration and use of enhanced elimination techniques have specific implications in the young pediatric patient.

CHAPTER

Obstetrics Toxicology

Sara Nooruddin Kazim, Mahra Nooruddin Kazim, Lara Abumuaileq, Azza Yousif

INTRODUCTION

Poisoning during pregnancy warrants special consideration. 0.6% of all calls to the poison control centers are related to exposure during pregnancy. Toxicity is not only on the mother but also on the fetus. The effect of toxicity on the fetus and mother can be due to the direct impact of the xenobiotic or can be secondary to changes in the maternal circulation. Hypoxia and hypotension, for example, affect fetal circulation and oxygenation and lead to fetal distress and miscarriage. Toxicity can result from either intentional or unintentional exposure. More than 80% of calls to poison control centers are related to unintentional exposure. Intentional exposure represents 50% of severe cases that warrant hospitalization. Over-the-counter analgesics and sedatives are the two most common classes of intentional drug exposure during pregnancy. The risk factors for deliberate overdose include young maternal age (<30 years), early pregnancy (first trimester), smoking and drug misuse, history of miscarriage, and mental illness. Overdose is one of the leading causes of maternal death and a cause of miscarriage early in pregnancy.

DRUG PHARMACOKINETICS DURING PREGNANCY

The physiological changes during pregnancy alter xenobiotic levels in the circulation. These changes affect xenobiotic in maternal and fetal blood concentrations. These changes relate to xenobiotics absorption, distribution, metabolism, and excretion. Xenobiotic absorption during pregnancy results in lower peak concentration due to nausea and vomiting, reduced gastrointestinal (GI) motility, and increase GI transient time. This effect is minimal with oral xenobiotics with repeated dosing. Drug distribution during pregnancy varies with the xenobiotic type. Low protein binding leads to an increase in the proportion of free xenobiotic in the circulation. Dose adjustment is essential in drugs such as phenytoin, valproic acid, and carbamazepine. An increase total body water during pregnancy increases the volume of distribution of water-soluble drugs and lowers the peak plasma concentration. The activity of xenobiotic-metabolizing enzymes is increased during pregnancy. For example, nifedipine, lamotrigine, and antiretroviral drugs will have lower therapeutic levels during pregnancy. Glomerular filtration and renal blood flow rates increase during pregnancy. However, this is counterbalanced with different rates of secretion and reabsorption. For example, lithium's clearance is doubled compared to 20–30% of digoxin clearance. The pharmacokinetic changes in pregnancy determine the blood flow to the fetus and the effect of these xenobiotics on the growing fetus.

PHARMACOLOGY OF DRUG TRANSFER ACROSS THE BLOOD–PLACENTAL BARRIER

Maternal and fetal blood is separated by a complex blood–placental barrier (BPB) regulating the movement of molecules and xenobiotics between the maternal and the fetal circulation. BPB controls the flow of xenobiotics to the fetal circulation and hence determines their implication on the fetus. However, the BPB does not function until the second half of pregnancy. Xenobiotics affect the fetus by affecting blood flow through the placenta or directly on the growing fetus. Beta-blockers reduce placental blood flow and affect fetal growth. Xenobiotics with a direct impact on the fetus cross the BPB by simple diffusion down their concentration gradient. The characteristics of xenobiotics that cross the BPB with are; low molecular weight (<500 Da), low protein binding (free drugs), high lipid solubility, and unionized drugs. Benzodiazepines, paracetamol, and opioids cross the BPB by simple diffusion. Xenobiotics also cross the BPB by active or facilitated diffusion (cephalosporins and glucocorticoids).

FETAL TOXICOLOGY

During the fetal period, organs continue their cellular differentiation and growth to functional systems. Most of the chemicals causing fetal developmental adverse outcomes are xenobiotics, i.e., exogenous chemicals. The reference organism does not utilize exogenous chemicals as nutrient materials. Xenobiotics are not essential for maintaining the normal physiologic or biochemical function and are not part of the conventional array of chemicals synthesized by the reference organism. The outcomes of maternal exposure to xenobiotics are directly linked to the stage of fetal development

and the sensitivity of that organ system to the toxic effect. Such exposure leads to an adverse impact varying from organ malformation, carcinogenesis, or even fetal demise.

ORGANOGENESIS

Organogenesis occurs during the embryonic stage of development between days 18 and 60 of gestation. Most gross malformations are determined before day 36, though genitourinary and craniofacial anomalies occur later. **Figure 1** demonstrates critical periods in fetal development.

TERATOGENESIS

Teratogenesis is defined as the dysgenesis of fetal organs as evidenced either structurally or functionally (e.g., brain functions). Adverse teratogenesis outcomes are restricted growth or death of the fetus, carcinogenesis, and malformations. Studies of reproductive toxicology are conducted on animals by administering a drug or a xenobiotic at the period of organogenesis. The outcome is compared to the outcome in untreated (control) animals. **Table 1** provides a list of drugs found to be teratogenic in humans with similar teratogenic effects in animals.

GENERAL APPROACH TO POISONING IN PREGNANT WOMEN

Early resuscitation and identification of reversible life-threatening conditions are crucial to optimize the management of overdose during pregnancy. Risk assessment is an essential phase of the management of xenobiotic toxicity. It identifies the xenobiotic's risk on the mother and the fetus. Management is mainly supportive with consideration of decontamination and antidote administration when indicated. The use of activated charcoal and whole-bowel irrigation is similar to nonpregnancy cases, and only after protecting the airway. Although there is no conclusive evidence for the safety of antidote uses during pregnancy, it is prudent always to weight the inconclusive teratogenicity of the antidote against the risk on the mother. Specific cures, such as naloxone or flumazenil, can precipitate severe withdrawal and lead to fetal distress. Prompt administration of an antidote is crucial whenever a maternal indication exists. Specific management of certain xenobiotics is described in the following section.

ACETAMINOPHEN

Acetaminophen overdose is common during pregnancy due to its excellent safety profile. One third of intentional overdoses in North America are secondary to nonopioid analgesics [(acetaminophen and non-steroidal anti-inflammatory drugs (NSAIDs)]. Much of the available information about acetaminophen poisoning during pregnancy is derived from case reports and case series. Acetaminophen crosses the BPB, and toxic levels were found in fetuses of women who had toxic acetaminophen levels.

The clinical presentation of acetaminophen toxicity in pregnant women is similar to that in the nonpregnant women. Early recognition of acetaminophen toxicity is the key to successful management and a good prognosis. Toxicity from acetaminophen occurs when metabolism through the nontoxic pathways is saturated, and N-acetyl-p-benzoquinoneimine (NAPQI) is produced through alternative routes. NAPQI is a toxic product causing liver necrosis (**Fig. 2**).

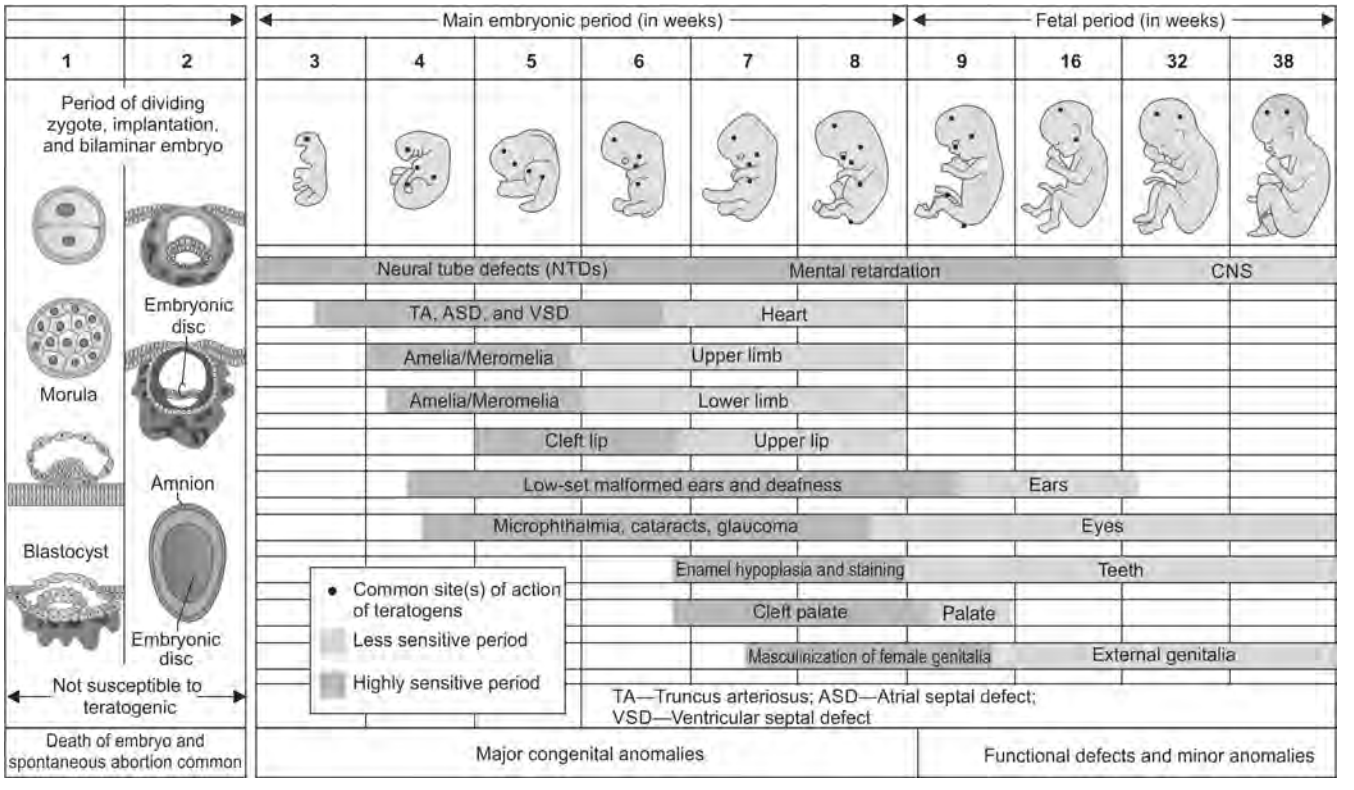

FIG. 1: Critical periods of human prenatal development.

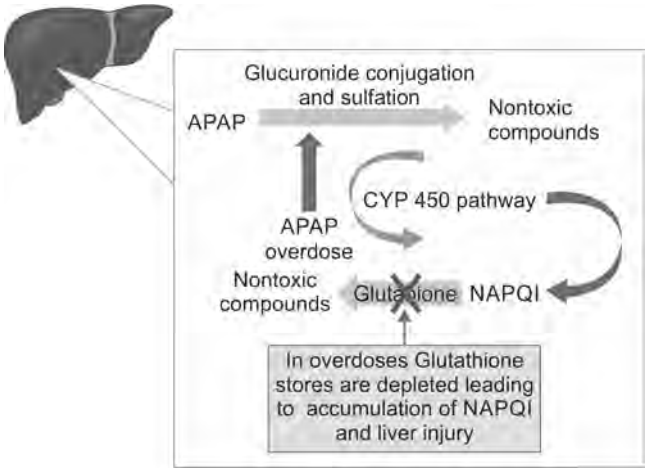
TABLE 1: Teratogenic effects of xenobiotics.

Drug	*Teratogenic effects (known, possible)*
Aminopterin, methotrexate (amethopterin)	CNS facial defects, malformed extremities or fingers, reduction in derivatives of the first branchial arch, developmental delay
Amiodarone	Transient neonatal hypothyroidism, with or without goiter; hyperthyroidism
Androgens	Virilization of the female external genitalia: Clitoromegaly, labioscrotal fusion
Angiotensin-converting-enzyme inhibitors	Prolonged renal failure in neonates, decreased skull ossification, renal tubular dysgenesis, fetal or neonatal death, prematurity, oligohydramnios, IUGR, secondary skull hypoplasia, limb contractures, pulmonary hypoplasia
Antithyroid drugs (propylthiouracil and methimazole)	Antithyroid drugs (propylthiouracil and methimazole)
Carbamazepine	Upslanting palpebral fissures, epicanthal folds, short nose with long philtrum, fingernail hypoplasia, developmental delay, neural- tube defects
Carbon monoxide	Cerebral atrophy, intellectual disability, microcephaly, convulsions, spastic disorders, intrauterine death
Cocaine	IUGR, microcephaly, neurobehavioral abnormalities, vascular disruptive phenomenon (limb amputation, cerebral infarction, visceral or urinary tract abnormalities)
Cyclophosphamide	CNS malformations, secondary cancer, Danazol and other androgenic drugs
Diazepam	Cleft palate
Diethylstilbestrol*	Vaginal carcinoma and other genitourinary defects in female and male offspring
Ethanol	Fetal alcohol syndrome (FAS): Pre- or postnatal growth retardation, intellectual disability, fine motor dysfunction, hyperactivity, microcephaly, maxillary hypoplasia, short palpebral fissures, hypoplastic philtrum, thinned upper lips, joint, digit anomalies
Fluconazole	Fluconazole craniofacial defects, humeral radial synostosis, femoral bowing
Hypoglycemic drugs	Neonatal hypoglycemia
Lithium	Ebstein's anomaly
Misoprostol	Moebius sequence
Nonsteroidal anti-inflammatory drugs	Constriction of the ductus arteriosus,† necrotizing enterocolitis
Paramethadione*	Facial and CNS defects
Paroxetine	Cardiovascular malformations, mostly VSD and ASD
Penicillamine	Cutis laxa, hyperflexibility of joints
Phenytoin	Fetal hydantoin syndrome: Microcephaly, intellectual disability, cleft lip or palate, hypoplastic nails, or phalanges, characteristic facies—low nasal bridge, inner epicanthal folds, ptosis, strabismus, hypertelorism, low-set ears, wide mouth
Psychoactive drugs (e.g., barbiturates and opioids)	Neonatal withdrawal syndrome when the drug is taken in late pregnancy
Quinine	Hypoplasia of eighth nerve, deafness, abortion
Ionizing radiation	Microcephaly, intellectual disability, eye anomalies, growth retardation, visceral malformations
Streptomycin	Hearing loss
Systemic retinoids (isotretinoin and etretinate)	CNS, craniofacial, cardiovascular, and other defects
Tetracycline	Anomalies of teeth and bone
Thalidomide	Limb-shortening defects, internal-organ defects
Trimethadione*	Facial and CNS defects
Valproic acid	Neural-tube defects
Vitamin D	Possible association with supravalvular aortic stenosis, elfin facies, and intellectual disability
Warfarin	Skeletal and CNS defects (fetal warfarin syndrome), Dandy–Walker syndrome

*The drug is not currently in clinical use.

†Sulindac probably does not have this effect.

(ASD: atrial septal defect; CNS: central nervous system; IUGR: intrauterine growth retardation; VSD: ventricular septal defect)



(APAP: acetaminophen; NAPQI: N-acetyl-p-benzoquinoneimine)

FIG. 2: Acetaminophen toxicity pathway.

Acetaminophen crosses the BPB, and fetal serum concentrations of acetaminophen are similar to maternal serum levels a few hours after acute ingestion. Fetal metabolism is unclear; however, the rate is insufficient to produce significant NAPQI levels due to immature cytochrome P450 pathways. Poor maternal and fetal prognosis is mainly due to late recognition and massive overdoses.

Early recognition of toxicity and rapid risk assessment are the keys to successful management of acetaminophen overdose. Early initiation of N-acetylcysteine (NAC) is crucial since NAC crosses the BPB and proves to be safe during pregnancy. Fetal complications are mainly related to maternal illness and delayed treatment of acetaminophen overdose by NAC.

ANTIDEPRESSANTS

Antidepressants are widely used during pregnancy. In the United States (US), the prevalence of antidepressant use among pregnant women is 8%. Studies in Europe report that 3% of pregnant women received antidepressants during their pregnancy. Selective serotonin reuptake inhibitors (SSRIs) are the most commonly prescribed antidepressants during pregnancy. During pregnancy, SSRIs' use is associated with preterm labor and postpartum hemorrhage. SSRIs do not increase the risk of hypertensive disorders of pregnancy or miscarriage. The majority of SSRIs are not associated with fetal congenital malformations or birth defects. However, there is an increased risk of cardiovascular defects, especially with the use of paroxetine.

IRON

Iron toxicity is among the 10 most common overdoses during pregnancy. While most multivitamins contain 15–18 mg of iron, the dose is remarkably higher in prenatal vitamins, reaching 60–65 mg of iron per tablet. While similar effects are seen in mothers with iron toxicity, a study on intentional iron overdose in pregnant women reported increased rates of spontaneous abortion, preterm delivery, and maternal death due to organ failure. There are no reports of direct toxicity on the fetus due to the saturable manner of placental absorption, which prevents iron from accumulating. The risk to the fetus presents when the mother develops multiorgan failure. Several case reports favor the use of deferoxamine in pregnancy for its safe outcome in both mother and fetus. Although animal studies reported skeletal anomalies with deferoxamine, these have not been described in humans. In one study on 24 pregnant women treated with deferoxamine for iron overload during organogenesis, only one case reported spontaneous abortion.

OVER-THE-COUNTER MEDICATIONS

Over-the-counter (OTC) medications are readily available for use. Although they do not cause clinically significant toxicity in overdose, some of these OTC medications can have significant toxicity, not only on the mother but also on the fetus.

Ibuprofen and Nonsteroidal Anti-inflammatory Drugs

One third of reports of pregnant women presenting to the emergency department with an overdose are nonopioid analgesics (acetaminophen and NSAIDs). Acute overdose from NSAIDs causes a minimally significant effect, with no evidence of fetal malformation. Hepatotoxicity and severe metabolic acidosis are reported in rare cases of overdose. In the third trimester, chronic exposure results in premature closure of the ductus arteriosus and oligohydramnios. Management is mainly supportive with one reported case in 2012 of treatment with hemodialysis in an intentional ibuprofen overdose in a pregnant woman.

Antihistamines

Diphenhydramine is commonly available as an OTC cold remedy. Intentional overdose results in significant toxicity. In addition to its effect as an anticholinergic and a sodium channel blocker agent in overdose, they have an oxytocin-like effect. They cause prolonged uterine tetany and fetal bradycardia. Management is mainly supportive, early resuscitation, and decontamination, especially in massive overdoses. Physostigmine is used as a potential antidote with variable results. However, physostigmine lowers the seizure threshold; thus, its use in pregnancy is unfavorable. Benzodiazepines and tocolytics are preferred in the treatment of toxicity from antihistamines.

Decongestants and Expectorants

Pseudoephedrine and dextromethorphan are commonly used decongestants in pregnancy. Pseudoephedrine causes elevated blood pressure and uterine arteries vasoconstriction. Its use in the first trimester is thought to be associated with gastroschisis. Cardiac dysrhythmia is described with pseudoephedrine toxicity. A 36-year-old, 19-week pregnant woman with a repeated supratherapeutic overdose developed ventricular arrhythmia. Management is mainly supportive in overdose cases.

Gastrointestinal Medications

Acute toxicity from gastrointestinal medications is rare. Toxicity is mainly described with chronic use. The two classes pregnant

women use during pregnancy are antidiarrheal agents and antacids, respectively. Bismuth-containing compounds are available OTC as antidiarrheal medication. Its use during pregnancy is controversial due to its effect on stimulating salicylate absorption. Salicylate causes premature closure of the ductus arteriosus. Acute kidney injury is described in cases of acute bismuth toxicity. A case report of a 16-year-old pregnant woman with acute bismuth overdose resulted in acute kidney injury. The patient received chelation therapy and renal replacement therapy. The patient had an uneventful recovery and delivered a healthy child. Aluminum hydroxide and cimetidine are common antacids used during pregnancy. Acute cimetidine has a benign toxicity profile, and management is mainly supportive. Chronic use of cimetidine is safe during pregnancy, and there is no conclusive teratogenic effect. Aluminum hydroxide antacids are poorly absorbed and are safe during pregnancy. Severe toxicity necessitates chelation therapy. There is no evidence of teratogenic effects from their use during pregnancy, and its use is safe when used for overdose cases. Drug–drug interaction is described between antacids and phenytoin. Antacids reduce the rate of phenytoin absorption and reduce plasma levels. Thus, phenytoin levels need to be monitored during pregnancy for better seizure control.

SUBSTANCE MISUSE

Heroin/Opioids

In the US, approximately 0.2% of pregnant women report heroin use, 0.8% report illicit use of prescription analgesics, and 0.1% report using oxycodone during pregnancy. Opioid misuse increases the risk of miscarriage, abruptio placentae, preeclampsia, premature rupture of membrane, and increased maternal cardiac events and septic thrombophlebitis. Fetal complications related to opioid misuse include intrauterine growth retardation (IUGR), preterm labor, and fetal demise. The American Society of Addiction Medicine and the American College of Obstetricians and Gynecologists suggest using methadone or buprenorphine for treating opioid misuse. Pharmacological therapy is superior to supervised withdrawal or heroin use and is associated with reduced incidents of maternal and neonatal withdrawal syndromes.

Cocaine

International studies suggest that the use of cocaine and other stimulants during pregnancy is increasing. Among pregnant women, 0.1% report using cocaine in the previous month. Cocaine use increases uterine vascular resistance in addition to oxidative injury from oxygen radicals and reperfusion injury. Acute cocaine use is associated with maternal cardiovascular complications and abruptio placentae. Other less common presentations include perinatal seizure, stroke, and intracerebral hemorrhage. Fetal exposure to cocaine caused IUGR and reduced birth weight, length, and head circumference. Other less common complications include genitourinary malformations, cardiovascular malformations, and limb-reduction defects. Cocaine use in the perinatal period leads to changes during early infancy and childhood, such as decreased muscle tone, reflexes, alertness, and cognition. Hydralazine is the preferred antihypertensive agent in treating hypertension in pregnant individuals who use cocaine.

Ethanol

The Center for Disease Control and Prevention (CDC) estimated that 7.3% of pregnant women are exposed to ethanol during pregnancy. The exposure rate is highest during the first trimester. Because there is no recommended safe ethanol level during pregnancy, medical societies recommend complete abstinence from alcohol use. Ethanol toxicity is mediated via direct cell necrosis from the oxidative effect of free radicals, alterations on serotonins, and development and function of N-methyl-D- aspartate (NMDA) receptors. During pregnancy, alcohol consumption increases the incidents of spontaneous abortion, preterm labor, stillbirths, and neonatal and maternal withdrawal symptoms. Fetal exposure during pregnancy is associated with fetal alcohol spectrum disorders (FASD). Severe FASD include intrauterine and postnatal growth retardation, intellectual disabilities, behavioral abnormalities, and facial dysmorphogenesis. Examples of facial dysmorphogenesis include micrognathia, epicanthal folds, maxillary hypoplasia, cleft palate, and microcephaly. Management of chronic ethanol abuse is multidisciplinary. It includes maternal and fetal surveillance, in addition to pharmacological and psychological support. Naltrexone is used in managing ethanol abuse disorders with no evidence of clinical toxicity.

Benzodiazepines

Although use of benzodiazepines during pregnancy is not associated with congenital malformations or congenital disabilities, their use in the first trimester is associated with miscarriage. Antenatal use of benzodiazepines is associated with preterm labor. Neonatal toxicity occurs with chronic maternal use of benzodiazepines during the third trimester. Examples of neonatal toxicity include low Apgar score, apnea, hypothermia, hyperreflexia, irritability, and poor feeding. Neonates are also at risk of developing benzodiazepine withdrawal that persists up to 3 months of age. Benzodiazepine withdrawal presents with tremor, diarrhea, poor feeding, or vomiting.

ANTICONVULSANTS

Approximately 0.3–0.8% of pregnant women have epilepsy requiring medical treatment. In every 200 pregnancies, at least one woman is treated with antiepileptic drugs. Valproate, phenytoin, and carbamazepine are all associated with major congenital malformation when used during the first trimester. The risk increases significantly with higher doses. Lamotrigine is commonly used due to its relatively safe effect during pregnancy; likewise, lamotrigine may cause major congenital malformation during the first trimester in doses higher than 325 mg/d. Also, anticonvulsants are associated with a higher risk of stillbirth and preterm delivery.

Women on anticonvulsants are at a high risk for antepartum and postpartum hemorrhage, and preeclampsia. The most significant finding in toxicity includes central nervous system depression, hypotension, and respiratory depression. Lamotrigine dose often needs to be increased in

late pregnancy because of an increase in the activity of liver metabolizing enzymes. Thus, the lamotrigine dose needs to be adjusted after delivery to avoid toxicity. Mothers affected present with altered mental status, ataxia, and nystagmus. Management is mainly supportive with fluid resuscitation, endotracheal intubation, and mechanical ventilation for altered mental status. Naloxone, which is considered safe in pregnancy, can be used in overdose cases with sodium valproate.

ANTICOAGULANTS

Use of most anticoagulants during pregnancy is associated with a teratogenic effect on the growing fetus. Nevertheless, pregnant women are at a high risk for thromboembolic events. Besides, some women need to be on long-term anticoagulation for conditions such as women with prosthetic valves. Fortunately, an anticoagulant overdose is not common during pregnancy. Toxicity results from molecules that cross the BPB, such as warfarin, and less likely with large molecules that do not cross the BPB, such as heparin and low-molecular-weight heparin. Toxicity results not only from an acute overdose but also from poorly controlled anticoagulation. The use of warfarin during the second or third trimester is associated with central nervous system anomalies and mental retardations. Spontaneous abortion, stillbirth, and death occur as well throughout pregnancy. Direct-acting oral anticoagulants (DOACs) use during pregnancy showed variable results. The use of apixaban is associated with a higher risk of spontaneous abortion than warfarin. However, data are inconclusive since most studies on DOACs excluded pregnant women from their research population. Management is supportive mainly with no reported contraindication for using vitamin K, fresh frozen plasma, and protamine to reverse the anticoagulant effect of warfarin and heparin.

CARBONE MONOXIDE

Carbon monoxide (CO) is a common substance involved in unintentional poisoning in North America during pregnancy. 13% of all accidental exposures during pregnancy are due to fumes, gases, and vapors. CO poisoning diagnosis is always a challenge since the symptoms are nonspecific, ranging from simple flu-like symptoms to seizures and come. Headache is almost always present in all cases of CO poisoning. CO poisoning causes tissues, hypoxia, and fetal distress. CO has a higher affinity for hemoglobin than oxygen and reduces tissue oxygenation (**Flowchart 1**). CO poisoning on the fetus is either due to the direct effect of CO on fetal blood or secondary to maternal systemic hypoxia. Fetal hypoxia results in miscarriage, stillbirth, and fetal neurological complications at birth. Management cornerstone is to remove the source of exposure and reduce CO half-life. Hyperbaric oxygen therapy (HBO) is safe and effective for lowering CO half-life. HBO has proven to be safe and effective during pregnancy for patients with CO poisoning.

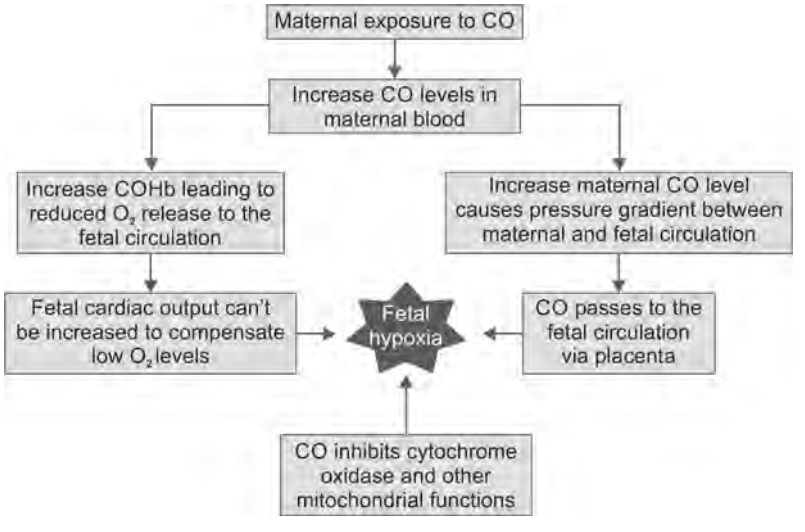
CARDIOVASCULAR DRUGS

Angiotensin-converting Enzyme Inhibitors, Angiotensin II Receptor Blockers

Exposure during the second or third trimester causes significant renal dysgenesis, oligohydramnios, and skull hypoplasia in fetuses. Excessive exposure in mothers can lead to hyperkalemia and severe hypotension. Management is mainly supportive of early resuscitation and management of hypotension. There is no known antidote for the management of toxicity.

Beta-blockers

Common drugs of choice for treating hypertension during pregnancy are also known to increase the risk of intrauterine growth retardation, preterm birth, fetal bradycardia, and hypoglycemia. In excessive doses, they cause hypotension, bradycardia, pulmonary edema, and cardiogenic shock. Cardiogenic shock reduces blood flow through the placenta and leads to fetal demise. Management is mainly supportive of early resuscitation. Glucagon does not cross the placenta and can be used in overdose cases. High-dose insulin euglycemia therapy can also be used in cases of cardiogenic shock.



Maternal exposure to CO
Increase CO levels in maternal blood
Increase COHb leading to reduced O_2 release to the fetal circulation
Increase maternal CO level causes pressure gradient between maternal and fetal circulation
Fetal cardiac output can't be increased to compensate low O_2 levels
Fetal hypoxia
CO passes to the fetal circulation via placenta
CO inhibits cytochrome oxidase and other mitochondrial functions

(CO: carbon monoxide)

FLOWCHART 1: Fetal carbon monoxide toxicity.

Calcium Channel Blockers

Exposure to calcium channel blockers during the third trimester of pregnancy increases the risk of neonatal seizures in infants. In acute toxicity, mothers suffer from significant hypotension, bradycardia, and cardiogenic shock. Management is mainly supportive and the use of calcium salts and high-dose insulin euglycemia therapy for severe cardiogenic shock.

Diuretic Agents

Diuretic agents are mostly safe in regular doses during pregnancy, although some studies reported low birth weight, thrombocytopenia, and neonatal jaundice while using hydrochlorothiazide. Acute toxicity causes hypovolemia and electrolyte imbalance. No known antidote or treatment is mainly supportive with fluid and electrolyte correction.

SUMMARY

The general approach to toxicity in pregnant women is similar to nonpregnant women. However, it is essential to understand the impact toxicity has on the mother and the growing fetus. Xenobiotics can cause either direct toxicity or indirect toxicity. Direct toxicity relates to xenobiotics that cross the BPB and exert their immediate effect on fetal tissue. At the same time, the indirect effect is mainly secondary to the hemodynamic effects of the xenobiotic. Hypotension and cardiogenic shock impair fetal blood flow and cause fetal demise. Resuscitation and risk assessment are the cornerstones for the successful management of patients with toxicity. Other essential factors to consider when dealing with drug toxicity and management are the changes in the drug pharmacokinetics and variable flow of a specific treatment (e.g., antidote) in crossing the BPB. Maternal resuscitation in case of toxicity is the ultimate goal in management and in supporting fetal circulation.

CHAPTER

Integrated Trauma System

Prasad Rajhans, Purushotham Godavarthy

INTRODUCTION AND EPIDEMIOLOGY

Trauma is defined as physical damage or harm to the body as a result of exposure to environmental, social, or behavioral determinants. Trauma is one of the leading causes of mortality, morbidity, and disability in younger population. It not only causes loss of precious lives but also imposes direct and indirect economic and social costs to the community. It is estimated that 1 million people die and 20 million are hospitalized every year due to various injuries in India. Amongst all the causes, road traffic accident (RTA) is one of the leading causes of trauma. According to the National Crime Records Bureau (NCRB), about 4,13,457 people died in road accidents in India in 2015. Injuries occur across a broad spectrum of events and the level of care delivered depends on the nature of injury, geographical location of the event, and availability of the resources.

CONCEPT OF AN INTEGRATED TRAUMA SYSTEM

An integrated trauma system is an organized and coordinated approach for care of the injured and includes prehospital emergency care, triaging, transportation, and definitive care of the injured. An ideal trauma system includes a continuum of medical services to provide seamless transition between each phase of care, integrating the existing resources of the public health systems within a definitive area to achieve improved patient outcomes. An integrated trauma system helps in appropriate and judicious use of available resources and delivers the best possible services within budget constraints. The "model trauma system policy" developed by the World Health Organization (WHO) envisages an *integrated approach toward trauma care* (**Flowchart 1**) and includes the following:

- Prehospital care
- Acute care facilities
- Posthospital care (rehabilitation)
- Injury prevention

The advantages of trauma system include the following:

- Evacuation of casualties to designated injury care facilities
- Reduction of injury incidence and severity
- Rigorous system performance improvement standards
- Cost containment and efficacy enhancement

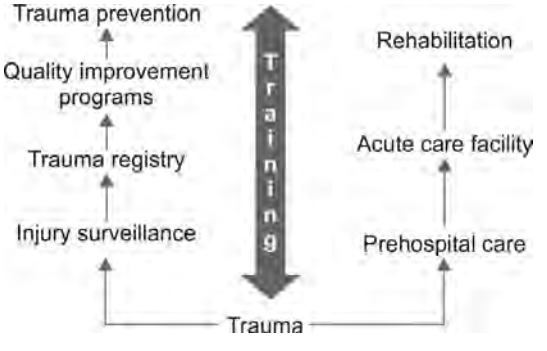
PREHOSPITAL TRAUMA CARE

The Golden Hour

"There is a golden hour between life and death. If you are critically injured you have less than 60 minutes to survive. You might not die right then; it may be three days or two weeks later --but something has happened in your body that is irreparable."

—R Adams Cowley

Prehospital trauma care involves trauma care at the site of incident and en route to definitive treatment facilities. Early identification and safe transportation of injured patients to an appropriate facility within the golden hour help in reduction of mortality and morbidity. Prehospital care is provided by emergency medical services (EMS) responders who are trained to recognize the nature of a disaster, evaluate the situation, and determine the need for resources, including medical resources. In India, the first responders are usually the bystanders, home guards, police, or the fire brigade who do the basic assessment and activate the EMS. Mortality due to injuries follows a trimodal phase of distribution and includes the following (**Fig. 1**):



FLOWCHART 1: Integrated approach for trauma management.

- Immediate—death occurs immediately within seconds or minutes as a result of overwhelming injury, e.g., injury to aorta, heart, brainstem, spinal cord, or acute respiratory distress.
- Early—death occurs within hours of the injury and is frequently the result of treatable conditions, e.g., hemorrhage, central nervous system (CNS) injury. These patients can be saved by appropriate treatment during the "golden hour."
- Late—death occurs in days or weeks after the initial injury and is the result of infection, multisystem failure, or other late complications of trauma.

Approaches to Prehospital Care

The elements of prehospital trauma include the following (**Table 1**):

- Communication and activation
- Response from the system
- Onsite care
- Care en route
- Transportation to a definitive medical facility

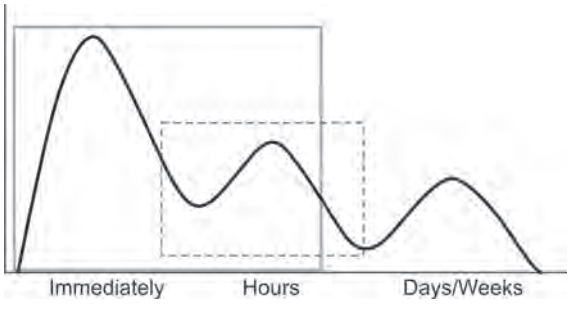


FIG. 1: Trimodal distribution of death.

Stay and play: The trauma team provides treatment and/or stabilization on scene before transporting the patient to the hospital. Few interventions include airway protection and intubation for securing airway, obtaining intravenous lines, starting the fluid resuscitation therapy, splinting of fractures, thoracotomy, administration of medications, etc.

Scoop and run: The patient is transported to the hospital as fast as possible by the trauma team after provision of basic care at the scene of accident. Both the approaches have advantages and disadvantages (**Table 2**).

Communication and Activation

Detection of injury and activation of emergency medical services: Immediately following an accident, bystanders, volunteers, or community health workers who are witnesses to the incident need to recognize the severity of accident and activate the EMS. In India, issues such as legal liability and ethical considerations dissuade bystanders from helping these victims. Initiatives such as Good Samaritan Law help in empowering people to aid injured people without fear of adverse consequences. There is multiplicity of services in India providing EMS including government and private players. The introduction of 108 calling service has simplified the activation of EMS.

Response from the System

Immediately on receiving call regarding the accident, the call center assigns an ambulance along with paramedical staff to reach the site of the accident. Training of call center staff in triaging, central location of ambulance vehicles, tagging with global positioning system (GPS) and public-private partnerships, etc., could help in faster response times of EMS.

TABLE 1: Components of prehospital care.

Prehospital care				
Core components		***Trauma care providers***	***Problems***	***Solutions***
Communication and activation		First responders	Legal issues, hesitation, ethical issues, delay in information	Training in BLS Good samaritan law
↓	Detection of injury	Bystanders, volunteers community health workers, home guards, fire brigade, police		
	Activation of EMS		Multiplictiy of services	Unified ambulance service (108 service)
Response from system				
↓	Dispatch of ambulance and trained manpower		Delay in dispatch, availability of resources	Central loction of ambulance, GPS mapping of ambulance, training of staff at call centers in triaging
Onsite care				
↓	Prehospital triage	Advanced trauma care (Paramedic/Nurses/EMS physician)	Availability of trained manpower	Training in trauma scoring system, ATLS
	BLS, First aid, Resuscitation		Availability of monitoring and medical resources	Upgradation of medical infrastructure
Care en route				
Transportation to definitive facility			Availability of definitive resources	Involvement of healthcare systems at various levels

(ATLS: advanced trauma life support; BLS: basic life support; EMS: emergency medical services; GPS: global positioning system)

Onsite Care

The onsite care is provided by the EMS team consisting of trained paramedics and doctors. Immediately on arrival at the site, scene management including clearing of traffic and hazardous material is carried out followed by initial assessment, field triage, and provision of basic first aid. Basic life support (BLS) including airway, breathing, and circulation is carried out and the patient is transported to a higher medical center.

TABLE 2: Advantages and disadvantages of strategy for transfer of patient.

Approach	*Advantages*	*Disadvantages*
Stay and play	Patient stabilized at scene of accident following principles of A, B, C	• Delay in definitive investigations and treatment • Requirement of trained manpower including EMS physicians
Scoop and run	Patient is transferred to definitive care as soon as possible where a team of multispecialty doctors can care for patient	• Delay during transportation like traffic • Availability of advanced ambulance vehicles for transport

(EMS: emergency medical services)

En Route Care

Patients being transported are constantly monitored and appropriate medical care is provided in the ambulance vehicle till they are taken to a healthcare facility.

Transportation to a Definitive Facility

Based on the mechanism of injury, field triage (**Table 3**), geographical location of accident, and availability of resources, a decision regarding the transportation of patient to a definitive center is taken and the patient is transported. In India, the level of care and facilities at different centers vary and include community health centers, district hospitals, medical colleges, and tertiary care centers. There is a requirement of close coordination between different agencies and EMS staff for faster transportation and to a definitive center as per the requirement and triage.

TABLE 3: Guidelines for field triage of injured patients.

Assess vital parameters and level of consciousness	• Glasgow Coma Scale • Systolic blood pressure (SBP) (mm Hg)	≤13 <90 mm Hg	Transfer to trauma center with multidisciplinary facilities—medical college/ university hospital/tertiary care center
	Respiratory rate	<10 or >29 breaths/min* (<20 in infant aged <1 year) or need for ventilatory support	
	NO		
Assess anatomy of injury	• All penetrating injuries to head, neck, torso, and extremities proximal to elbow or knee • Chest wall instability or deformity (e.g., flail chest) • Two or more proximal long-bone fractures • Crushed, degloved, mangled, or pulseless extremity • Amputation proximal to wrist or ankle • Pelvic fractures • Open or depressed skull fracture • Paralysis		
	NO		
Assess mechanism of Injury	• Falls: ○ Adults: >20 feet (one storey is equal to 10 feet) ○ Children†: >10 feet or two or three times the height of the child • High-risk auto-crash: ○ Intrusion‡, including roof: >12 inches occupant site; >18 inches any site ○ Ejection (partial or complete) from automobile ○ Death in same passenger compartment ○ Vehicle telemetry data consistent with a high risk of injury • Auto versus pedestrian/bicyclist thrown, run over, or with significant (>20 mph) impact§ • Motorcycle crash >20 mph		• Transfer to any trauma center with facilities • Community health center/ university hospital/ medical college/tertiary hospital depending upon time involved
	NO		

Continued

Continued

Assess special patient or system considerations	• Older adults:[††]
	  ○ Risk of injury/death increases after age 55 years
	  ○ SBP < 110 mm Hg might represent shock after age 65 years
	  ○ Low impact mechanisms (e.g., ground-level falls) might result in severe injury
	• Children: Should be triaged preferentially to pediatric capable trauma centers
	• Anticoagulants and bleeding disorders: Patients with head injury are at a high risk for rapid deterioration
	• Burns:
	  ○ Without other trauma mechanism: Triage to burn facility[¶]
	  ○ With trauma mechanism: Triage to trauma center[¶]
	• Pregnancy >20 weeks
	• EMS provider judgment
		• Consult with control room
		• Transport to the trauma center or hospital capable of timely and thorough evaluation and initial management of potentially serious injuries

When in doubt transport to trauma center		

*The upper limit of respiratory rate in infants is >29 breaths/min to maintain a higher level of overtriage for infants.

[†]Age < 15 years.

[‡]Intrusion refers to interior compartment intrusion, as opposed to deformation which refers to exterior damage.

[§]Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact > 20 mph with a motor vehicle.

[††]Age > 55 years.

[¶]Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma patient presents a greater immediate risk, he/she may be stabilized in a trauma center and then transferred to a burn center.

(EMS: emergency medical services)

ACUTE CARE FACILITIES

Code Trauma

A trauma center is a medical facility having a team of multidisciplinary professionals and specialized resources available round the clock to care for victims with critical injuries. The level of trauma center is defined based on the availability of resources and manpower.

Trauma Team Definition

A trauma team is a group of multidisciplinary healthcare workers who work together as a team to assess and manage severely injured patients. The aim of the team is to rapidly resuscitate and stabilize the patient and reduce the time to diagnosis and treatment with the overall objective of improving survival rates. The team consists of specialists from emergency medicine, surgery, anesthesia, intensive care, orthopedics, nursing, and allied health and support staff coordinated by a team leader (**Fig. 2**).

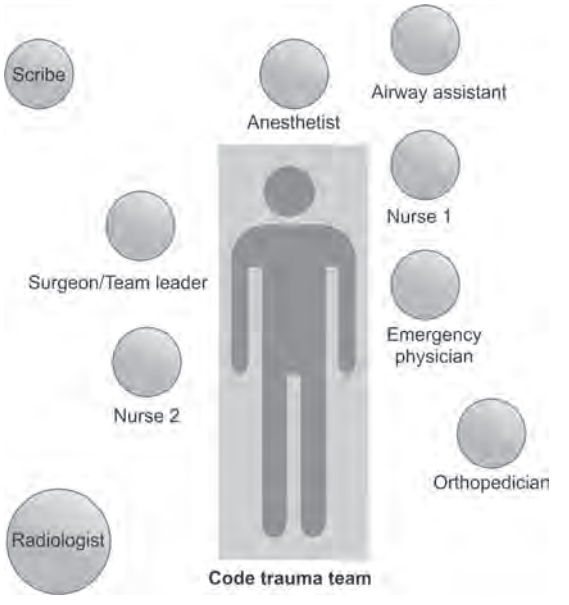

FIG. 2: Code trauma team.

Composition of Team

- Team leader—trauma surgeon/emergency physician
- Emergency physician
- Anesthetist
- Trauma trained nurse
- Radiographer
- Operation room staff
- Scribe/data recorder
- Social worker/manager

Other members as per availability and requirement are:

- Orthopedic surgeon
- Neurosurgeon
- Vascular surgeon
- Laboratory medicine
- Blood bank

Based on the information about the type of trauma, the team meets before the patient reaches the trauma center. Upon arrival, initial assessment and resuscitation are carried as per defined protocol. Trauma centers must clearly define the following (role and responsibilities) (**Box 1**):

- Who all constitute the trauma team?
- When must the team assemble?
- Where must the team assemble?
- Whom to respond?
- Team leader

BOX 1: Roles and responsibilities of trauma team members.

Team leader—trauma surgeon/ER physician

The team leader is usually a trauma surgeon or ER physician who takes all diagnostic and therapeutic decisions regarding the patient. Responsibilities of a team leader include:

- Assesses hospital notification and activates trauma team if trauma criteria are met
- Trauma checklist and prearrival team briefing prior to every trauma presentation
- Discusses potential injuries, procedures, and treatment prior to arrival of patient
- Allocates roles and tasks according to skill and experience
- Presence of all assigned team members and activation of backup plan in case of any absence
- Ensures that requisite drugs, material, and equipment are readily available and functional
- All the team members don personal protection equipment (PPE) and other precautions.
- Ensures good team communication through use of clear and concise statements, along with closed-loop communication
- Ensures correct documentation and handing over of patient to another team leader on completion of duty

Assessment—trauma surgeon/ER physician

- Donning of PPE
- Transfer of patient to ED trolley
- Primary survey:
  - Airway and cervical spine
  - Breathing
  - Circulation
  - Disability
  - Exposure and environment
- Reassess patient; if unstable shift immediately to operating room/trauma center. If stable, carry out the secondary survey.
- Secondary survey—patients' history and physical examination
- Reassure patient on arrival, explain what is happening
- Clearly state findings to team leader, nurse, and scribe
- Order required investigations through nurse
- Delivery of required medication

Airway lead—anesthetist/airway assistant

- Donning PPE
- Check the preintubation checklist; prepare equipment and drugs and difficult airway cart
- Discusses airway plan and backup plan with team leader and nurse
- Cervical spine immobilization during transfer and assessment
- Airway assessment
- Definitive care—intubation/cricothyroidotomy/LMA, etc.
- Places patient on ventilator support
- Sedation and appropriate during ventilation
- Accompanies patient during intra- and inter-hospital transfer

Trauma nurse

- Don PPE
- Transfer of patient to ED trolley
- Attach patient monitors and oxygen if required
- Establish IV access
- Collect samples for investigations
- Administration of medications
- Prepares and checks procedure trolleys
- Assists in various procedures such as intercostal chest drainage
- Liaison with various departments for bed management
- Liaison with blood bank, laboratory

Radiographer

- Prior loading of X-ray plates
- Patient positioning
- X-ray for primary survey (chest X-ray, cervical spine)
- X-ray for secondary survey
- Preparation for transfer to CT scan facility

Scribe

- Documents of trauma team members, their time of arrival, and allocated roles
- Time of patient arrival and details
- Examination findings of primary and secondary assessment
- Recording of vital signs
- Record of drugs/intravenous fluids and blood administration

(CT: computed tomography; ED: emergency department; ER: emergency room; IV: intravenous; LMA: laryngeal mask airway)

- Who all should respond during a particular incident?
- Communication about the trauma

Criteria for Activation of Trauma Code

Though there are no definitive criteria for activation of trauma code, the team leader based on information received during field triage, mechanism of injury, anatomy of injury, physiological parameters of patients, and other factors at his/her discretion can activate the trauma code (**Table 4**).

Advantages of Trauma Code

- Early mobilization and involvement of more experienced medical staff
- Shorter time to primary and secondary surveys and to performing diagnostic investigations
- Reduction in time from injury to critical interventions due to distribution of tasks in assessment
- Effective communication, supervision, leadership attributes influencing clinical outcomes
- The introduction of trauma teams has improved patient outcomes. Data from Petrie and colleagues showed that patients with an injury severity score (ISS) > 12 had a significantly better outcome when a trauma team was activated than when they were treated on service-by-service basis.

REHABILITATION

Patients sustain disabilities of speech, cognition, neurological deficits, locomotor activities, and psychosocial functioning following life-threatening injuries and require rehabilitation care. Nearly 100% of those with severe injuries,

TABLE 4: Criteria for activation of trauma code.

Mechanism of injury	
Motor vehicle accident	• Speed over 80 km/h • Ejection/rollover/trapped • Unrestrained/fatality
Two-wheeler	Any with speed >30 km/h
Fall from height	• Adult >3 m and/or five stairs • Elderly on anticoagulant therapy
Physical assaults	Shooting, stabbing or blunt trauma, head injury with GCS <13
Others	Bomb explosion, hanging, drowning
Type of injury	• Airway injuries/obstruction/respiratory distress • Penetrating injury to the head/neck/chest/abdomen/pelvis/back/limbs • Burns >10% BSA
Physiological	• Respiratory rate <10 or >30 • Blood pressure <90 mm Hg systolic at any stage • Heart rate <40 or >120 • GCS <14
Others	• Pregnant patient with trauma • Infants • Transfer from other hospitals

(BSA: body surface area; GCS: Glasgow Coma Scale)

50% of those with moderate injuries, and 10–20% of those with minor injuries carry disabilities of a physical and/or psychological nature requiring long-term rehabilitation services. Patients with ventilator dependence, tracheostomy, or other similar conditions are sent to skilled nursing facilities while those with brain or spinal cord injuries are sent to inpatient facilities for an intensive rehabilitation program. Patients with minor conditions such as limb trauma, fractures, or other bony injuries are discharged to continue rehabilitation at outpatient rehabilitation services.

INJURY EPIDEMIOLOGY AND PREVENTION

Injuries are caused by a complex interaction between human beings, environment (roads, infrastructure), and agents (vehicle, product). Studying the causes and burden of injuries is crucial to understanding the magnitude of the problem and developing mechanisms for intervention and allocation of resources (physical, financial, and human resources) to control and prevent them. Injury prevention and control is an intersectoral activity requiring inputs from different agencies such as the police, road transport agencies, municipalities, health departments, media, and others. Governments, community organizations, and trauma centers need to implement coordinated injury prevention programs that address the most common injuries in a community, region or state and the population group (e.g., children, elders, teen drivers, specific occupations, etc.) in which they occur and which are important to reduce the number of injuries in the population.

SUMMARY

An integrated trauma system is a need of the local public health system in which an organized, coordinated effort and full range of care is delivered to all injured patients in a defined geographic area. With integration of existing resources to achieve improved patient outcomes, the true success of a trauma system is defined by seamless transition between each phase of care. Trauma system can be initiated region wise by using efficient health care resources. Trauma systems are based on the requirements of the particular group of population such as rural, sub-urban, urban. In the context of community health every trauma system must emphasize the prevention of injuries. Success of a trauma system is largely determined by the degree to which it is supported by public policy. Ultimately, nationwide development of trauma systems would allow for seamless and effective trauma care of injured across the nation with the ability to expand to meet the medical needs of the community.

219
CHAPTER

Initial Assessment and Management of Polytrauma

Sanjay Shah

INTRODUCTION

India, the world's largest democracy and the second most populous country, is in the midst of an economic boon and hence in the phase of domestic product growth and hike in the standard of living. But unfortunately, despite this overall economic growth, we are still lacking in an effective system of delivering trauma care and emergency services to the majority of our citizens. There is an overall increase in the incidence of polytrauma as a consequence of increased urbanization and industrialization. The *World Health Organization* (WHO) has predicted that trauma-related deaths in India would move up from the ninth position up to the third position by the year 2020. The National Crime Records Bureau in India reported that in 2010, at least 10.1% of deaths were due to road traffic accidents and injuries. There were a total of 6,78,326 cases of accidents, which caused 3,59,583 deaths and 5,03,932 people were rendered injured and the affected population belonged to the productive age group—15 to 44 years. This chapter outlines the steps in the assessment and management of polytrauma patients. The main *objectives of the chapter are*:

- To identify the *correct sequence of priorities* for assessment of the polytrauma patient and *triage*
- To know and apply the principles outlined in *primary and secondary surveys*
- To apply guidelines and techniques to *initial management and definitive care*
- To correlate the patient's *medical history and mechanism of injury* with the identification of injuries
- To *re-evaluate,* when the patient is not responding appropriately to resuscitation and management
- To understand the importance of *teamwork and* recognize patients who require *safe transfer* for definitive management

TRIMODAL DISTRIBUTION OF TRAUMA MORTALITY

A person may get injured by various modes such as road traffic accident, fall from height, assault or thermal and blast injury. These *injuries may give rise to three patterns of death*: (1) Immediate, (2) early, and (3) late death (**Fig. 1**).

Immediate deaths: These deaths usually occur within the first hour and include death on spots. Major vascular, brain, and cardiac injuries are the main causes. About 50% of trauma-related deaths are immediate deaths.

Early deaths: Deaths occurring within hours are included in early deaths. The main causes are hemorrhage and breathing issues.

Late deaths: These deaths occur after 3 days and peak at 3–4 weeks. The main causes are sepsis and multiorgan failure. It is very important to have a robust trauma management system at both prehospital and in-hospital stages. The preparation for a trauma patient in two different clinical settings is described below.

Prehospital phase: This phase refers to field management. It includes the following principles of *intervention at the injury site:* Resuscitation and evaluation of the trauma patient begin at the injury site. The goal is to get the right patient to the right hospital at the right time for definitive care without any delay. In the stay and play approach, the patient receives treatment and stabilization on scene before being transported to the hospital (airway maintenance, control of external bleeding and shock, immobilization of patient). Scoop and run is the approach where the patient is transported to the hospital as soon as possible without making efforts to stabilize him/her at the scene. A scoop and run principle is better than stay

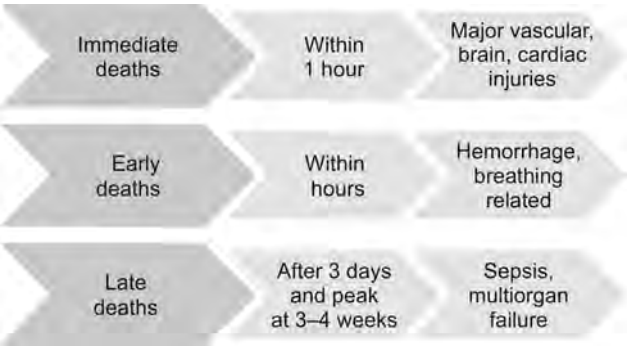

FIG. 1: Trimodal distribution of deaths in polytrauma.

and play in prehospital settings. It is important to notify the receiving hospital before transport of patient from the scene so as to allow time for mobilization of personnel and resources beforehand only.

Hospital phase: It includes the following: A resuscitation area should be made available. Airway equipment should be organized, checked, and placed in an accessible location. Warmed intravenous crystalloid solutions should be made available. Appropriate monitoring devices should be available. Additional medical assistance should be called for. Laboratory and radiology personnel should be notified. Standard precaution gears are mandatory due to concerns of communicable diseases. Management of life-threatening trauma must be prioritized according to physiologic necessity for survival, that is, active efforts to support airway, breathing, and circulation (ABC). The systematic management of a polytrauma patient, i.e., triaging, primary survey, resuscitation, secondary survey and monitoring, definitive treatment, and transfer in the emergency department (ED), is described in the following text.

PRIMARY SURVEY AND INITIAL RESUSCITATION

During initial assessment, an empirical sequence of lifesaving therapeutic and diagnostic procedures is pursued. The goal is to establish adequate oxygen delivery to the vital organs. In most of the tertiary care hospitals, primary survey and resuscitation go hand in hand by a team of trained doctors and nurses. The primary survey consists of five important steps:

1. Airway with restriction of cervical spine movement
2. Breathing and ventilation
3. Circulation and control of hemorrhage
4. Disability
5. Exposure and control of environment

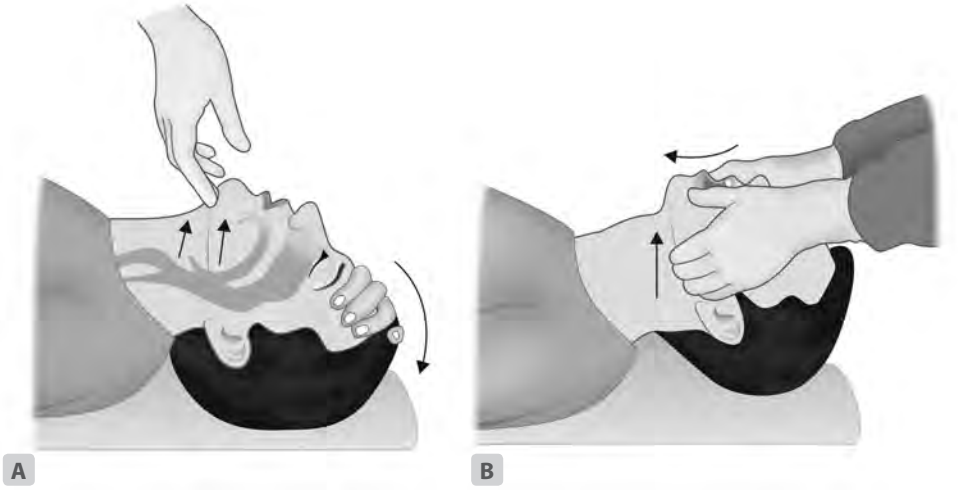
Airway with Restriction of Cervical Spine Movement

In cases of polytrauma, airway control should proceed along with the assumption that there is an injury to the cervical spine in all patients and hence, extension of the neck must be avoided. Evaluation begins by asking the patient "How are you?" A response given in a normal voice indicates that the airway is not in immediate jeopardy, whereas a breathless, hoarse response or no response at all indicates that the airway may be compromised.

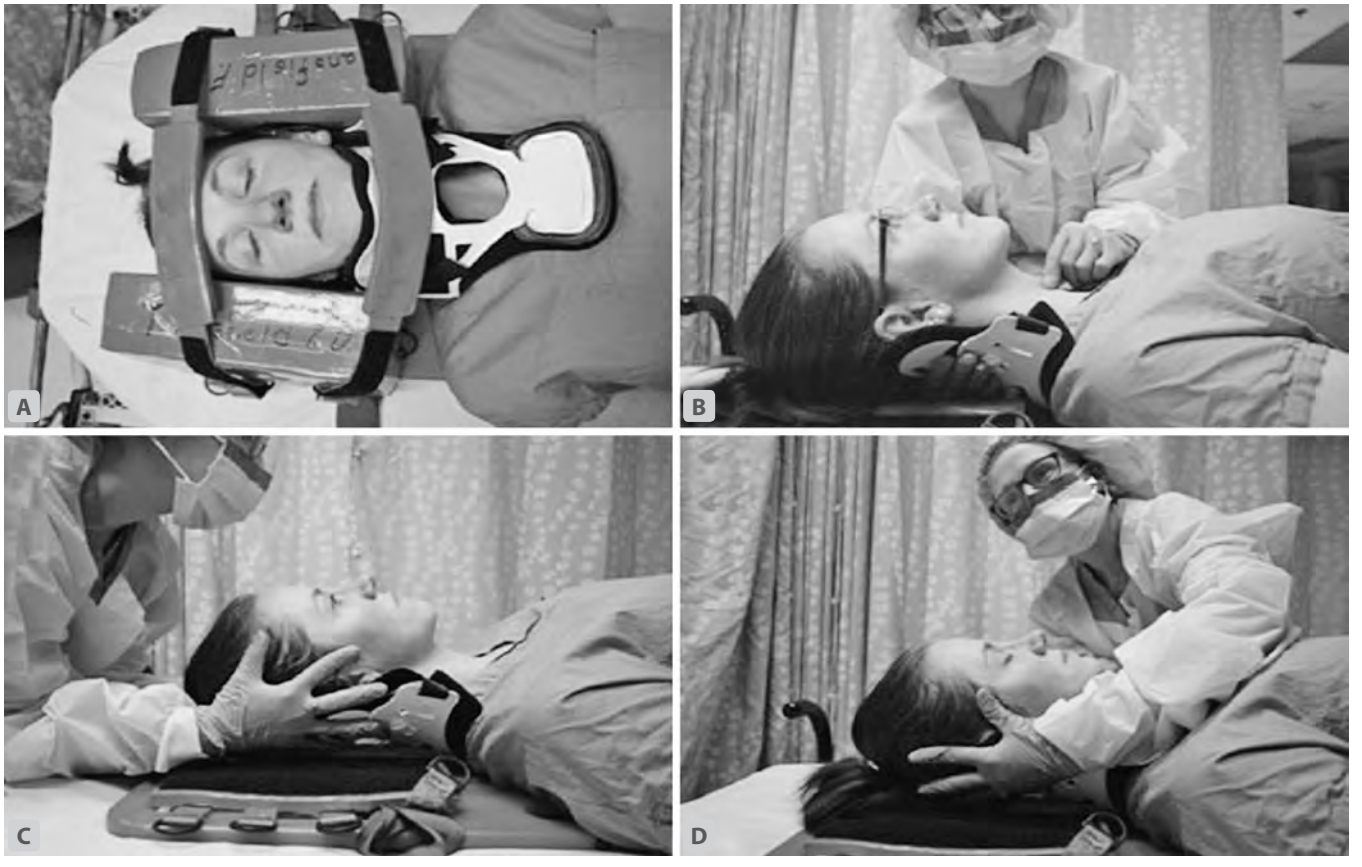
Airway obstruction and hypoventilation are the most likely causes of respiratory failure. The critical decision is whether active airway intervention is needed or not. The first maneuver is to clear the airway of debris and to suction secretions. In the obtunded patient, this procedure is followed by elevation of the angle of the mandible (head-tilt, chin-lift, or jaw-thrust; **Figs. 2A** and **B**) to alleviate pharyngeal obstruction and placement of an oropharyngeal or nasopharyngeal airway to maintain airway patency. Supplemental oxygen is given via a nonrebreathing oxygen mask at 10–12 L/min. Cervical spine protection is integral to airway management but should not be allowed to delay necessary intervention (**Figs. 3A** to **D**). Bag-mask ventilation is an effective temporizing measure, but it consumes the attention of a skilled trauma team member, it may insufflate air into the stomach, and it can be resisted by spontaneously breathing patients. It is also ineffective in the presence of severe maxillofacial trauma.

The decision for urgent airway control is made on clinical grounds. Persistent airway obstruction or signs of inadequate ventilation mandate prompt intervention. Patients with expanding neck hematomas, deteriorating vital signs, or severe head trauma are also best managed with an aggressive airway approach. Patients in respiratory distress with severe maxillofacial trauma may warrant a surgical airway. Cricothyroidotomy is the preferred approach in adults and has replaced tracheostomy in the ED. The rare exceptions are in rapidly deteriorating patients with extensive laryngeal trauma or tracheal disruption.

In all other patients, the current standard approach is rapid-sequence intubation (RSI) of the trachea orally with in-line immobilization. In adults, a large (8-mm internal diameter) cuffed endotracheal tube is inserted to a distance of 23 cm from the incisors. In children, the tube size is gauged to equal the diameter of the little finger. The proper depth (in centimeters) to which the tube should be inserted can be estimated by multiplying the tube's internal diameter (in millimeters) by 3. After successful intubation, re-examination of the patient must be done for bilateral chest rise, five-point



FIGS. 2A AND B: (A) Head tilt-chinlift; (B) Jaw-thrust maneuver.



FIGS. 3A TO D: Cervical spine protection by immobilization.

auscultation, and confirmation with presence of end-tidal carbon dioxide ($ETCO_2$) waveform on the monitor. A chest X-ray should be obtained as soon as possible to rule out the possibility of right mainstem intubation.

Breathing and Ventilation

Rapid assessment of chest examination should be carried out by inspection, palpation, and auscultation (percussion is discouraged in a trauma patient as it is painful and not able to give conclusive findings). Also, look for trachea which shall be central and jugular venous pressure (JVP). Patients who are having severe tachypnea, raised JVP, deviation of trachea on the opposite side, and hypotension should be immediately diagnosed as tension pneumothorax. In such adult patients, immediate needle thoracocentesis via a large-bore over the needle catheter (12–14 G) in the intercostal space, anterior to the mid-axillary line, is done followed by intercostal tube drainage. In pediatric patients, needle thoracocentesis is done in the 2nd intercostal space with the midclavicular line on the affected side. Suspected hemopneumothorax should be vented immediately with large-bore chest tubes inserted in the 5th intercostal space, anterior to the midaxillary line in unstable patients. Clinical evidence of hypoventilation includes poor air exchange at the nose and mouth, diminished breath sounds, and decreased chest wall excursion. The most likely causes are head injury, spinal cord injury, hemopneumothorax, flail chest, and profound shock. Extended FAST (focused assessment with sonography in trauma) is a very useful point-of-care test available with the emergency physician to diagnose pneumothorax, hemothorax, and pericardial tamponade. Intubated patients should be placed on a high fraction of inspired oxygen (FiO_2), and their SaO_2 should be monitored by pulse oximetry. In cases of lung injury patients who are on a ventilator, low tidal volume, low *positive end-expiratory pressure* (PEEP), and higher respiratory rate shall be kept to prevent further barotrauma. Hyperventilation should also be avoided. A low arterial carbon dioxide tension ($PaCO_2$) can cause cerebral vasoconstriction, which can be deleterious in patients with traumatic brain injury (TBI). An arterial blood gas (ABG) analysis should be obtained to assess pH, $PaCO_2$, and base deficit.

Circulation and Control of Hemorrhage

Once alveolar ventilation is ensured, the next priority is to optimize oxygen delivery by maximizing cardiovascular performance. External hemorrhage shall be controlled by means of manual compression, elevation of limb, and if required by tourniquet in field area remote from hospital but should not be >90 minutes' duration. If the patient arrives in shock or has obvious multiple injuries, a short 16 or 18 French venous access should be taken in each antecubital vein. Intraosseous infusion through a cannula placed in the medullary cavity of a long bone is a safe and effective method for emergency vascular access in infants and children younger than 6 years. This procedure is typically performed in the anteromedial aspect of the tibia in an uninjured extremity; the distal femur, the distal tibia, and the sternum are other potential sites. Intraosseous infusion generally allows administration of sufficient fluid to facilitate subsequent access of peripheral venous cannulation.

With establishment of the first IV line, blood should be drawn for hematocrit, white blood cell (WBC) count, electrolyte, blood group type and cross-match, and coagulation profile in most of the polytrauma patients. 1 L of warmed isotonic crystalloid (20 mL/kg in children) is used for initial resuscitation in the ED. Lactated Ringer (LR) solution is preferred to normal saline (NS) unless the patient has an obvious brain injury. Excessive early administration of crystalloids has been identified as a risk factor for adverse outcomes; hence, the amount infused should be monitored closely. If the patient does not respond to crystalloid infusion at levels exceeding 30 mL/kg, blood should be administered. Early empirical blood transfusions are indicated in patients who arrive in severe shock (class III or IV hypovolemic shock) or who have injuries associated with significant bleeding (e.g., a vertical shear pelvic fracture or multiple long bones fractures), especially if the patients are elderly. Type-specific blood should be available within 20 minutes. If type-specific blood is not available, reconstituted O-negative packed red blood cells (PRBCs) may be used.

Disability

After adequate resuscitation, it is required to assess the patient's neurological status. The initial Glasgow coma scale (GCS) may not be correct as the patient may be in shock but it works as baseline GCS on presentation and needs to be documented. Assess the pupillary size on both sides and its reaction to light bilaterally. Monitoring of the patient's neurological status by assessing GCS and pupil examination is very important to identify rapid deterioration in neurology. If the patient's GCS < 8, then airway protection via an endotracheal tube is of utmost importance to prevent hypoxia and aspiration.

Exposure and Control of Environment

Complete exposure of all polytrauma is very essential to identify certain missed injury, especially in the penetrating injury group. Penetrating injury in axilla, back, gluteal cleft, and perineum is easily missed if the patient is not exposed completely and log rolled. After complete exposure and assessment, one needs to take care for prevention of hypothermia. Secondary to severe hemorrhagic shock and resuscitation with IV fluids stored at ambient temperature, hypothermia may occur. Moderate hypothermia (<32°C) causes platelet sequestration and inhibits the release of platelet factors that are important in the intrinsic clotting pathway. Core temperature often falls insidiously because of exposure at the scene and in the ED and because of administration of resuscitation fluids stored at ambient temperature. The first step is to prevent further heat loss by covering with blankets and infusing warm blood and fluid. Active external rewarming with heating blankets and increased room temperature should also be employed.

Evaluation and Continued Resuscitation

Identification of hemodynamic instability, recognizing the presence of shock, and assessing its severity are key factors in early decision-making. During the initial ABCs, palpation for the presence of pulses can be used to get a rough estimate of systolic blood pressure (SBP). In general, a radial pulse is detected when SBP is >80 mm Hg, a femoral pulse when SBP is >70 mm Hg, and a carotid pulse when SBP exceeds 60 mm Hg. The initial blood pressure (BP) measurement should be made with a manual cuff; automatic cuff BP measurement machines may overestimate SBP in hypovolemic trauma patients. An SBP < 90 mm Hg in conjunction with a heart rate > 130 beats/min is generally considered indicative of major shock. Most patients, however, especially young ones, can compensate for hypovolemia and maintain a normal BP even in case of significant ongoing hemorrhage.

The initial hemoglobin level is also notoriously misleading, either because the patient has not yet been adequately resuscitated or because there has not been sufficient time for influx of interstitial fluid into the intravascular space. It is more informative to measure the hemoglobin level again after initial volume loading for purposes of comparison.

Management of Nonresponsive Unstable Patients

Shock that persists despite initial volume loading may be due to severe hypovolemia, cardiogenic causes, or neurogenic causes. Given that neurogenic shock is fairly well tolerated, the key concern at this point is to quickly distinguish hypovolemic shock from cardiogenic shock because cardiogenic shock may necessitate immediate ED intervention. This distinction can usually be made by measuring *central venous pressure* (CVP) in conjunction with physical examination. In hypovolemic shock, CVP is generally <5 mm Hg, whereas in clinically significant cardiogenic shock, CVP usually exceeds 20 mm Hg.

The differential diagnosis of traumatic cardiogenic shock depends on the mechanism of injury and may include tension pneumothorax (**Fig. 4**), pericardial tamponade (**Fig. 5**), myocardial contusion, and air embolism. Typical physical signs may be difficult to appreciate in a noisy ED and timely diagnosis requires a high index of suspicion. Tension pneumothorax, the most common cause of cardiogenic shock in both blunt and penetrating trauma, is treated with emergency chest tube placement.

In traumatic pericardial tamponade, the classic components of the Beck triad (hypotension, muffled heart sounds, and raised JVP) are frequently absent, and pulsus paradoxus is rarely detectable. ED ultrasonography is the first test employed by emergency physicians in patients with high-risk penetrating wounds. Occasionally, a blunt trauma

FIG. 4: Tension pneumothorax.

FIG. 5: Cardiac tamponade.

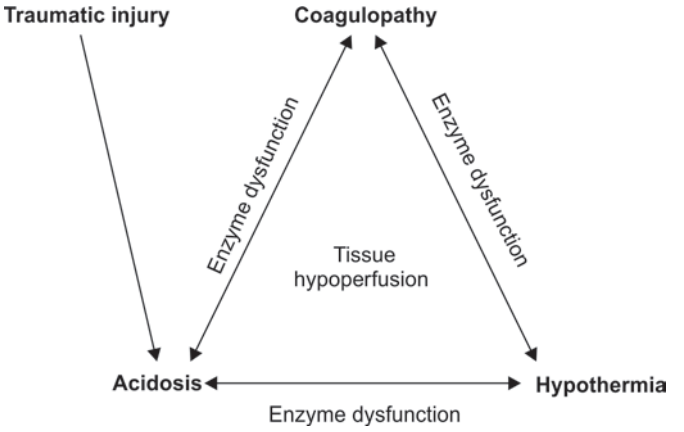


FIG. 6: The lethal triad.

patient can be salvaged through timely diagnosis of a blunt atrial tear. Myocardial contusion should be suspected in any blunt trauma patient with unexplained cardiogenic shock or persistent arrhythmia. ECG changes and elevated troponin levels are usually nonspecific. Fundamental interventions include correction of acidosis, hypoxia, and electrolyte abnormalities; judicious administration of fluid; and pharmacologic suppression of life-threatening arrhythmias. Bronchovenous air embolism into the left atrium from a pulmonary laceration typically occurs after penetrating trauma and is more common than is generally detected. Hemodynamic instability develops after positive-pressure ventilation is initiated as air is forced from the pulmonary bronchioles into the adjacent open pulmonary veins and, ultimately, into the coronary arteries. ED thoracotomy is essential for pulmonary hilar cross-clamping, air aspiration from the left ventricle, and cardiac massage. The patient is then transferred to the operation theater for definitive management of the pulmonary lesion before the hilar clamp is released.

Emergency department thoracotomy is an integral part of the initial management of the patient who deteriorates to imminent cardiac arrest. The physiologic rationale is to minimize the duration of profound shock. ED thoracotomy permits release of pericardial tamponade, internal cardiac massage, cross-clamping of the descending thoracic aorta to enhance coronary and cerebral perfusion and to reduce subdiaphragmatic bleeding, and control of intrathoracic blood loss. Internal cardiac massage should be done bimanually; otherwise, a forceful thumb may rupture the relatively thin right ventricle as it becomes distended.

Damage Control Resuscitation

Damage control resuscitation (DCR) is a strategy that emphasizes to maintain or restore homeostasis in trauma patients. The name "damage control" was coined from naval tactics aimed to keep a damaged ship as combat-capable as possible until definite repair can be done. The concept goes hand in hand with damage control surgery. The major threats in DCR are acidosis, coagulopathy, and hypothermia which makes a forward feedback loop that leads to progressive worsening of a patient's hemodynamic status and eventually death (**Fig. 6**). Lactic acidosis is a result of tissue hypoxia or hypoperfusion when the patient is in shock. Coagulopathy in polytrauma patients is multifactorial. It occurs when the enzymes that cause blood to clot are unable to function or due to deficiency of clotting factors. So, it may be due to overconsumption of clotting factors called consumptive coagulopathy. Additionally, infusion of crystalloids deficient of clotting factors aggravates this by causing dilution. Metabolic acidosis and hypothermia further worsen this coagulopathy. Identifying which patients will require DCR is very difficult but one can predict its requirement with anatomical and physiological criteria. Anatomic parameters for DCR include: injury severity score > 36, penetrating neck, chest or abdominal injuries, unstable pelvic fracture, multiple long bone fracture with head injury, or traumatic amputation above wrist or ankle. Physiologic parameters include: weak or absent radial pulse, core body temperature <35°C, SBP < 100 mm Hg, and heart rate >100.

Damage control resuscitation is also known as hypotensive resuscitation and hemostatic resuscitation. Appropriate fluid administration might help to maintain homeostasis. Inappropriate fluid administration will do just the opposite. In cases of penetrating trauma to the torso, research shows that withholding isotonic IV fluid had a mortality benefit. Hence, it is assumed that the benefit may come from decreased dilatational coagulopathy and hemostatic maintenance. However, in head injury patients, this strategy of allowing a low BP and restricting fluid is contraindicated. The key point is that resuscitation with a minimum amount of isotonic fluid needed to maintain mental status or mean arterial pressure of 65 mm Hg is probably the best strategy for patients without a significant head injury. Transfusion of blood products is potentially lifesaving for polytrauma patients. The ideal initial ratio for the massive transfusion of blood products is generally accepted to be one unit of fresh frozen plasma (FFP) to one unit of platelets to one unit of PRBCs (1:1:1). At many centers, it is lowered at a ratio of platelets and plasma to packed cells 1:1:2. Early transfusion with blood products, especially early plasma transfusion, is more beneficial than high volume isotonic fluid and it reduces mortality in polytrauma patients significantly.

Pharmacologic treatments that may have a role in treating trauma-induced coagulopathy include: prothrombin complex concentrate (PCC), cryoprecipitate, calcium, and tranexamic acid (TXA). PCC is used to reverse pharmaceutical anticoagulation. Cryoprecipitate contains clotting factors VIII

and XIII in addition to fibrinogen and von Willebrand factor. Calcium is essential in the clotting cascade for conversion of factor X to factor Xa and for the conversion of prothrombin to thrombin; both of these steps are critical for blood clot formation. With increasing early blood product use, trauma victims are at a risk of hypocalcemia. Also, calcium helps to increase myocardial contractility resulting in increased BP. TXA stabilizes blood clots by competitively binding to the lysine-binding site on plasminogen and preventing its conversion to plasmin. This stops clot breakdown and hence helps to reduce bleeding. As per the CRASH-2 (clinical randomization of an antifibrinolytic in significant hemorrhage 2) trial, the dosage in adult patients is 1 g loading over 10–15 minutes and 1 g in IV infusion over the next 8 hours when the patient has presented with 3 hours from time of injury.

SECONDARY SURVEY

Further assessment and management are governed by the initial severity of shock and its response to ongoing resuscitation. Life-threatening injuries should be addressed first followed by limb-threatening injury and finally, a search is made for occult trauma. Prioritization is also guided by the mechanism of injury. Penetrating trauma typically results in a localized injury, whereas blunt trauma frequently results in multiple injuries involving several body regions. When hemodynamic instability recurs, the underlying cause must be identified and corrected promptly by going back to primary survey. The length of time spent in the ED, the decision for urgent operation, and the ordering of special radiologic studies are critical decisions that must take into account the mechanism of injury, the severity of shock, and the availability of an operation theater with well-trained staff. The following regions should be examined from top to bottom to prevent missed injuries: Head, face, neck, chest, abdomen, pelvis, each extremity, detailed central nervous system (CNS) examination, spine, and perineum examination including per rectal and per vaginal.

Penetrating Trauma

Systematic Assessment

The secondary survey is more focused on cases of penetrating trauma, but the most common error is failure to identify multiple injuries. The priorities are (1) to identify all of the wounds, (2) to decide whether an urgent operation is indicated, and (3) to determine whether further investigations are needed to assist with intraoperative management. The decision-making process is driven by hemodynamic stability and the location of the wounds. Efforts should focus not only on resuscitating the patient until vital signs are normal but, rather, on obtaining adequate IV access, ensuring that blood products are available, and notifying the operating room (OR). Hemodynamically unstable patients should be rapidly sent to the OR with minimal testing. Any delay in doing unnecessary investigations will be adversely affecting the final outcome. The most valuable tests are plain X-rays to determine missile trajectory. Any impaled foreign body such as knife or rod which has caused a penetrating injury must never be pulled out in the emergency room (ER) else it can cause torrential life-threatening bleeding which may not be possible to control in ER.

Neck

Patients who have an obvious life-threatening penetrating injury (e.g., a gurgling wound, pulsatile bleeding, or a compromised airway) or are in severe shock should undergo operation theater promptly. ED management should be limited to airway control, external compression to control bleeding, IV access, and chest X-ray. A neurologic examination should be performed and documented in the event of a spine or carotid artery injury. Management of hemodynamically stable patients without an obvious injury is selective. Patients with zone I wounds should undergo computed tomographic angiography (CTA) scanning or angiography to rule out occult vascular injuries. Alert patients with zone II injuries but without significant hematoma, crepitation, dysphonia, or dysphagia may be managed expectantly. The exception is a transverse gunshot wound (GSW) where computed tomography (CT) scanning is usually done because of the high risk of an occult injury. Symptomatic patients with zone III injuries should undergo CTA scanning or angiography to assess for arterial injury that may warrant angioembolization.

Chest

In unstable patients with thoracic injuries, a chest tube should be placed into affected hemithorax, followed by a chest X-ray to confirm tube placement, lung expansion, and the presence of foreign bodies. If a cardiac wound is suspected, ED ultrasonography should be performed. Persistent instability without evidence of intrathoracic bleeding or pericardial tamponade should raise the suspicion of intra-abdominal bleeding. Occasionally, a thoracic spinal cord injury contributes to hemodynamic instability. The challenge in this setting is to quickly identify those patients who require an urgent operation.

Patients with documented pericardial tamponade and persistent tachycardia should undergo pericardiocentesis to relieve any ongoing subendocardial ischemia even if the SBP is normal, and a pigtailed catheter is inserted for repeated aspiration during transport to the OR. Patients who exhibit persistent signs of pericardial tamponade (e.g., CVP > 20 mm Hg) despite negative results from ultrasonography should be transported to the OR for creation of a subxiphoid pericardial window. If the patient is in extremis or deteriorates suddenly, ED thoracotomy should be performed promptly. Most patients diagnosed with intrathoracic bleeding outside the pericardium stabilize after tube thoracostomy and fluid resuscitation.

Urgent thoracotomy is indicated for massive hemithorax where an initial chest tube output is higher than 1,500 mL in an adult (20 mL/kg in children) or a persistent output is higher than 200 mL/h for 3–4 hours. Patients with an initial chest tube output higher than 10 mL/kg should be closely observed for hemodynamic instability in the intensive care unit (ICU). Abrupt cessation of chest tube output may be deceptive; if hypotension persists or recurs, a new chest tube should be inserted. Patients with large air leaks, massive subcutaneous emphysema, or a persistent pneumothorax may require high-resolution computed tomography (HRCT) or bronchoscopy to exclude a tracheobronchial injury. Patients with transmediastinal GSW or penetrating wounds close to the great vessels should undergo a CT scan with IV contrast and angiography. Lower chest wounds located below the nipples anteriorly or the tips of the scapula posteriorly may penetrate the diaphragm and cause significant intra-abdominal or retroperitoneal injuries. If the patient is unstable,

tube thoracostomy, chest X-ray, and FAST are indicated. If instability persists, the patient should be transported to the OR. If the patient stabilizes after tube thoracostomy, additional testing must be done to exclude associated injuries.

Anterior Abdomen

Unstable patients should be transported to the OR with minimal resuscitation and testing. Biplanar abdominal X-rays are often helpful in clarifying bullet trajectories; entrance and exit wounds should be marked with radiopaque objects. Management of stable patients depends on the mechanism of injury. Although there is some enthusiasm for selective nonoperative management of GSWs, laparotomy is generally recommended for GSWs that violate the peritoneal cavity. Contrast-enhanced computed tomography (CECT) of the abdomen or laparoscopy is indicated for suspicious tangential GSWs. Laparotomy is indicated in patients with overt peritonitis after a stab wound. In other patients, the stab wound should be explored. If there is no violation of the anterior fascia, the patient can safely be discharged. If the fascia is violated, the patient should be admitted for serial clinical assessments and further investigations.

Retroperitoneal Structures

Unstable patients with injuries to the flank, the back, or the pelvis should undergo immediate laparotomy. Stable patients are difficult to evaluate. With the exception of blood on rectal examination, the findings from physical examination are unreliable. Gross hematuria is indicative of bladder or kidney injury. Triple contrast CT scanning may be helpful in patients with high-risk wounds. Most retroperitoneal colon injuries are identified on the basis of extraluminal gas or fluid rather than of contrast extravasation. Sigmoidoscopy should be performed if a rectal injury is suspected. High-risk wounds should be explored to ensure that retroperitoneal colon injuries are not missed. Delayed diagnosis is associated with significant morbidity. Hence, stable patients with stab wound of flank are to be admitted for serial physical examination and intervention if required.

Extremities

Unstable patients with isolated penetrating injuries to the extremities should be managed with external compression to control bleeding. Blind clamping for vascular injuries should not be done because it may inadvertently cause injury to the adjacent vein or nerve. IV access with moderate volume resuscitation, compression bandage over the bleeding site, and prompt triage to the OR for exploration and definitive treatment is the best approach. Inappropriate use of tourniquets can cause considerable harm. Although extremity injuries are common in civilian trauma, death from extremity exsanguination is uncommon. Management of stable patients with penetrating extremity injuries begins with a search for *"hard" signs of arterial injury* (e.g., an expanding or pulsatile hematoma, absent distal pulses, a palpable thrill, an audible bruit, or signs of distal ischemia). The presence of any of these hard signs prompts further evaluation. If signs of distal ischemia exist, the patient should be taken to the OR, where on-table angiography is performed to identify the injury site. If knowledge of the patient's specific vascular anatomy is needed and no signs of ischemia exist, a formal angiography is reasonable. If *"soft" signs of vascular injury* (i.e., a history of arterial bleeding prior to ED admission, wound proximity to an artery, small nonpulsatile hematoma over the artery, nerve deficit originating in a nerve adjacent to the artery) are present, distal BPs should be measured in the injured extremity and nonaffected extremity. If the ratio of the BP in the injured extremity to that in the contralateral extremity is 0.90 or higher, arterial injury is virtually excluded and no additional testing is needed. These patients can be discharged from the ED but should follow up in the outpatient clinic because a small percentage will eventually come to operation as the original undetected injury progresses rather than heals. These ratios are not, however, reliable for excluding arterial injuries in the axilla or the groin. Furthermore, the presence of a "good" Doppler signal does not exclude an arterial injury.

Blunt Trauma

Systematic Assessment

The goal is to identify all potentially life- and limb-threatening injuries. A comprehensive assessment is crucial to facilitate triage from the ED to the OR, the CT scanning suite, the interventional radiology suite, or the ICU. The details of the patient's medical history, as well as the details specifically related to the injury, are critical. The prehospital emergency medical technicians are encouraged to provide comprehensive details of the event and a thorough patient assessment. A minimal review of the patient's medical history should include AMPLE, i.e., history of known allergy, current medications (especially anticoagulation status in the elderly), past medical illnesses, the time of the last meal, and event/mechanism that caused injury. A detailed systematic physical examination is done, from head to toe and front to back. Patients are completely disrobed and log rolled from side to side so that the back and the flanks can be inspected. A rectal examination is done to look for blood and to evaluate sphincter tone; the perineum and the axillae are inspected; and neurologic function and peripheral pulses are documented. The cervical spine is rigidly immobilized, and long-bone fractures are splinted to minimize pain, blood loss, and softtissue damage. Insertion of a gastric tube decompresses the stomach and reduces the risk of pulmonary aspiration. In patients with a maxillofacial injury, the tube should be placed orally to avoid intracranial insertion from the nasal route. Blood in the gastric aspirate may be the only sign of an otherwise occult injury to the stomach or the duodenum.

Placement of an indwelling catheter empties the bladder and permits output monitoring. Also, one can easily watch for frank hematuria if the color is red. The catheter should not, however, be inserted until abdominal ultrasonography is completed, and it should not be placed on an urgent basis in male patients with suspected urethral injuries (i.e., those with blood at the meatus, a perineal hematoma, a high-riding prostate, or an extensively displaced anterior pelvic fracture; **Figs. 7A** and **B**). If a urethral injury is suspected, a retrograde urethrogram, followed by a cystogram (to exclude bladder injury), is obtained before catheterization. In females, the urethra is shorter and better protected and thus is rarely injured. Routine X-rays performed simultaneously with the ABCs include anteroposterior chest and pelvic films. CT scanning has virtually replaced plain X-rays for

FIGS. 7A AND B: Pelvic fracture. (A) Open book fracture; (B) Pubic ramus fracture.

diagnosing potential spinal injuries. Once life-threatening injuries have been addressed, X-rays of extremities with suspected fractures (including the joint above and the joint below) should also be obtained. Given that trauma victims are uniquely susceptible to hypothermia, a rectal temperature probe is essential in those who have been exposed to a cold environment or who require massive volume replacement. At core temperature reading <35°C, re-warming measures appropriate for the degree of hypothermia should be initiated. Tetanus prophylaxis is routine. Systemic antibiotics should be given as per the hospital's antibiogram. An ECG is obtained after blunt chest trauma, and an ABG analysis is done in selected patients to confirm adequate ventilation and metabolic balance. In patients with evidence of hypovolemia, a blood sample should be sent for blood-group typing and coagulation studies.

Rapid Hemorrhage Control

Blunt trauma patients who arrive in shock and remain hemodynamically unstable pose difficult triage decisions. Initial screening must be directed at identifying life-threatening bleeding that necessitates immediate intervention. Most hospitals do not have an interventional radiology suite immediately available; early notification is crucial in assembling the team. There are only five causes of severe bleeding leading to hypovolemic shock, that is one on the floor (external bleeding) and four more (intrathoracic, intra-abdominal, pelvic and retroperitoneum, and long bone fracture). A chest X-ray is the most reliable screening test for intrathoracic bleeding; it also confirms the location of endotracheal, nasogastric, and thoracostomy tubes as well as that of the central venous catheter. The presence of pleural fluid may be difficult to confirm on a supine chest X-ray: A total of 1 L blood may produce only a hazy appearance in a hemithorax. Hemothoraces should be drained promptly via tube thoracostomy. Continued bleeding must be monitored carefully by measuring chest tube output, obtaining serial chest films to detect retained intrapleural blood, and observing vital signs. The criteria used to decide when thoracotomy is indicated are similar to those used in cases of penetrating trauma, but far fewer blunt trauma patients meet these criteria, and intrathoracic bleeding is rarely a reason for immediate OR triage.

The abdomen is difficult to evaluate and is much more likely than the chest to harbor occult life-threatening bleeding. The peritoneal cavity can accommodate as much as 3 L of blood with only minimal abdominal distention. Head injury or intoxication frequently alters the patient's response to acute injury, and pain from associated fractures may mask peritoneal irritation secondary to bleeding. Ultrasonography is the most rapid method of identifying free blood, but it fails to determine the source of blood and may yield false-negative results in as many as 15% of patients on initial examination. Assessment of bony stability by means of physical examination and plain films of the pelvis is crucial for the early identification of major pelvic fractures. Life-threatening hemorrhage occurs most commonly with fracture patterns involving the posterior columns. Appropriate initial management of unstable patients who have a high-risk pelvic fracture on the initial pelvic X-ray includes blood volume replacement (including early blood and FFP) and application of a pelvic binder; wrapping with a sheet is also effective. The next step is to evaluate the response to initial resuscitation and then perform FAST or diagnostic peritoneal lavage (DPL) to determine whether significant intra-abdominal bleeding is present. DPL is a good screening test for intra-abdominal injuries in unstable patients where FAST is not available. Laparotomy is performed if there is free aspiration of blood, gastrointestinal contents, vegetable fibers, bile or red blood cell counts > 100,000/mm^3, >500 WBC/mm^3 or positive Gram stain for bacteria. Left-sided penetrating injuries should be pursued more aggressively because of the increased risk of delayed visceral herniation. A CT scan may assist in diagnosing occult retroperitoneal injuries but is not reliable for excluding penetrating diaphragmatic injuries.

An unstable patient with clearly positive findings from FAST or DPL should undergo laparotomy because of the high probability of major hepatic, splenic, or mesenteric bleeding. If there is a large pelvic hematoma at the time of laparotomy and the patient is unstable, extraperitoneal pelvic packing should be done. The role of pelvic packing versus angioembolization is controversial, but these modalities should be viewed as complementary.

Fast-track CT Scanning

In patients who became stable after resuscitation, the priorities are to (1) identify and quantitate ongoing sources of bleeding, identify TBI, especially in those patients who require immediate craniotomy; and identify any other injuries that call for urgent intervention [e.g., thoracic aortic injury (TAI) or special precautions (e.g., spine fractures)]. With the wide-

spread availability of CT scanners in proximity to the ED, rapid whole-body imaging is now feasible, permitting accurate triage for these competing priorities. The decision to order CT scanning is made early, while the ABCs are being addressed and FAST and initial plain X-rays are being performed, any obvious injuries identified, and the patient's hemodynamics are stabilized. Whenever the patient is being sent for CT scan of brain, always go for CT cervical spine screening to rule out cervical spine injury as it is more confirmatory than X-rays as well as less time-consuming. For abdominal injuries, always ask for contrast-enhanced triple-phase CT scan of abdomen to get complete information. For chest injuries, usually HRCT plain is sufficient but if the patient has signs of active bleeding or is suspected of mediastinal injury, always do CTA.

Identification of Abdominal Injuries

The decision to perform an urgent laparotomy in a patient with a positive FAST depends on the patient's hemodynamic stability. A CT scan can be helpful in refining the triage category by identifying extravasation of IV contrast (i.e., a blush) and in diagnosing hollow viscus injuries. A blush should prompt consideration of angiography and embolization, if available, or surgical intervention. Early angiography is a helpful adjunct in managing liver, spleen, and kidney. Hollow viscus injury is sometimes notoriously difficult to diagnose. Extravasation of oral contrast is rare; hence, it should not be given. When all signs (e.g., unexplained free fluid, bowel wall thickening, mesenteric streaking, and free air) are considered, the sensitivity of CT scan in making the diagnosis approaches 90%. In questionable cases of a hollow viscus injury in stabilized patients, DPL is useful to determine elevations in WBC count, amylase level, and alkaline phosphatase level. Pancreatic injury is also poorly defined on the initial CT scan. A rising lipase warrants repeat CT scanning (and consideration for endoscopic retrograde cholangiopancreatography or magnetic retrograde cholangiopancreatography). However, in such a patient, serial physical examination by an experienced surgeon is very important for decision-making for further plan of management.

Identification of Traumatic Brain Injury

After ABC, a detailed neurological examination should be done by assessing GCS and pupillary examination to light. Also, GCS evaluation shall be repeated after resuscitation and frequently to be done as required and to be documented. Short-acting sedatives or paralytics should be given sparingly. A GCS score < 8 and a lateralizing neurologic examination indicate a significant risk that emergency craniotomy will be needed and, therefore, justify obtaining a CT scan of the head if hemodynamic stability permits.

Identification of Limb Ischemia

The absence of distal pulses in a fractured or dislocated extremity should be addressed urgently. Fractures and dislocations should be reduced, and the extremity should be closely examined for signs of ischemia. Distal SBP measurements comparing injured limbs with noninjured limbs [i.e., the ankle–ankle index (AAI) or the ankle–brachial index (ABI)] should be obtained. If the ABI or AAI is <0.90 after reduction, CTA should be performed to exclude the presence of an arterial injury if the patient is stable. In an unstable patient, a bedside Doppler examination is very important to rule out vascular injury. A detailed neurovascular examination is required before and after immobilization of fractured extremity.

SUMMARY

There is an overall increase in the incidence of polytrauma as a consequence of increased urbanization and industrialization. Important steps in managing the polytrauma are *correct sequence of priorities* for the assessment of the polytrauma patient and *triage: Primary and secondary surveys, initial management and definitive care, medical history and mechanism of injury* with the identification of injuries. *Re-evaluate,* when patient is not responding appropriately to resuscitation and management. Understand the importance of *teamwork and* recognize patients who require *safe transfer* for definitive management.

CHAPTER

Trauma Resuscitation

Ankur Verma

INTRODUCTION

Trauma is one of the most dynamic entities undergoing continuous research over the past many decades. Trauma resuscitation has evolved over the years from a singular approach for all to one customized to patients' physiologies. Yet, resuscitation protocols in trauma will never remain stagnant. Ongoing research will modify the guidelines for future trauma management. That is how dynamic trauma is. Trauma resuscitation is a complex process involving multiple team members (or sometimes just one or two) with various roles, simultaneous evaluations, examinations, management, and disposition in a coordinated manner. Until the development of the now famous advanced trauma life support (ATLS) courses, trauma was managed in a very heterogenous manner by physicians who lacked any trauma training. In 1980, the ATLS course was adopted by the American College of Surgeons and was taught throughout the USA and later adopted by the UK in 1988. The course eventually spread throughout the world and became a standard requirement to be completed by members of trauma teams across the globe. ATLS facilitated a common language among trauma care providers. It emphasized the importance of a team approach and introduced the airway-breathing-circulation-disability-exposure (A-B-C-D-E) sequence to trauma care.

The ATLS sequence of A-B-C-D-E provided a direction and structure to trauma caregivers in the management of major traumas. But the strict adherence to the approach has been questioned in recent times. For example, in recent times the concept of the physiologically difficult airway has been recognized and accepted by many. Management of the physiological disturbances in the human body before securing an airway is being emphasized upon. In trauma, the ATLS would still recommend to secure an airway before managing the shock and preintubation resuscitation. ATLS as a basic course to provide guidance and direction in trauma management is what we recommend.

In this chapter, we attempt to provide the latest evidence-based approach to trauma etiology, pathophysiology, and resuscitation.

SCIENCE BEHIND TRAUMA RESUSCITATION

Blood loss and traumatic brain injury (TBI) are the two leading causes of mortality following trauma. The above two are responsible for more than three fourths of injury-related deaths. Hemorrhagic shock and trauma-induced coagulopathy (TIC) are responsible for >50% of trauma-related deaths alone. Most preventable in-hospital deaths in trauma are attributed to uncontrolled hemorrhage and resultant coagulopathies.

Trauma-induced coagulopathy is a hypercoagulable state which occurs in the most severely injured patients. Acute traumatic coagulopathy (ATC) is an endogenous coagulopathy which may be present in approximately a fourth of patients wheeled into the emergency department (ED). Patients presenting with ATC are four times more likely to die, require massive transfusion, and develop multiple organ failure. ATC is induced by the combination of trauma and shock and is driven by the degree of tissue hypoperfusion. The underlying mechanism appears to include a systemic activation of the anticoagulant protein C pathway and generation of activated protein C. This leads to a reduction in thrombin generation through the inhibition of factors V and VIII, reduced fibrinogen utilization, and hyperfibrinolysis. ATC also seems to cause platelet dysfunction, with reduced aggregation in response to all standard activators, although platelet count is typically maintained after trauma. In other words, TIC/ATC is a multifactorial failure of the coagulation cascade to adequately achieve and sustain hemostasis in massively hemorrhaging trauma patients.

The process of TIC is further augmented by resuscitation-induced coagulopathy which may dominate later in the clinical course. Resuscitation coagulopathy triggers a progressive reduction in procoagulant factors further complicating ATC. Crystalloid and colloid infusions so enthusiastically infused will rapidly dilute circulating coagulation factors, especially when circulating blood volume is already low. This will further worsen the coagulopathy and prognosis for the bleeding trauma patient. Major trauma patients will mostly

present with an established endogenous coagulopathy, which is exacerbated by resuscitation in the face of ongoing bleeding. Damage control resuscitation (DCR) focuses on maintaining the hemostatic potential of blood, by minimizing any resuscitation-induced coagulopathy and correcting any existing coagulopathy. A "resequenced" approach to trauma along with DCR would help the trauma team to manage patients much better and achieve more favorable outcomes for the patient.

RESEQUENCED APPROACH

Case: A 50-year-old male construction worker has a fall from the second floor of a construction site. His Glasgow Coma Scale (GCS) score in the field is 12. In the ED, you evaluate the patient as per the ATLS protocol. His vitals are as follows: Respiratory rate (RR) 28 breaths/min, O_2 saturation 90% on 100% oxygen, heart rate (HR) 115 beats/min (bpm), blood pressure (BP) 103/80 mm Hg, and temperature 98.8°F. His airway is assessed to be patent, and air entry is decreased in the right chest. A focused assessment with sonography in trauma (FAST) examination is positive for free fluid in the right and left upper quadrants. His pelvis is mechanically stable. The peripheral neurologic examination is normal. He has no past medical history, takes no medications, and has no drug allergies.

As per the protocol, your team and you approach the patient in the following sequence:

1. Intubate the patient expecting poor clinical course
2. Chest tube placement
3. Blood product administration and 1–2 L of crystalloid infusion as initial bolus

As soon as you intubate the patient, the BP drops to 60 mm Hg systolic. Suspecting a tension pneumothorax, you do a needle decompression and infuse another liter of crystalloids for the shock. The systolic pressure does not rise till blood products are administered and tranexamic acid (TXA) is given. He is shifted to the radiology department for a computed tomography (CT) scan where his pressure drops again and more blood and fluids are given. He is diagnosed with a frontal hematoma with right-sided pneumothorax with liver and splenic lacerations.

In the "resequenced" approach (**Flowchart 1**), the trauma team needs to address key management priorities. The above mentioned patient requires intubation urgently *but not* immediately, as he is self-ventilating with an oxygen saturation of 90% and is protecting his airway. With a positive FAST and shock index (SI) >1.0, the team leader should choose to achieve hemodynamic optimization before rapid-sequence intubation (RSI), specifically a presumed right-sided tension pneumothorax and intra-abdominal injury. Studies have shown that unstable preintubation hemodynamic if not corrected can lead to devastating outcomes for the patient. These range from severe cardiovascular collapse to cardiac arrests. Optimization and resuscitation prior to endotracheal intubation are now becoming a norm. Resuscitation followed by intubation is also now commonly known as resuscitation-sequence intubation. An important clue to the presence of shock and occult shock is the SI which is defined as the HR divided by the systolic blood pressure (SBP). It is sensitive for predicting critical bleeding, the need for blood products, and the incidence of postintubation hypotension. The team leader should use the resequenced approach by outlining management priorities in the following sequence:

1. Blood product administration and massive transfusion protocol (MTP) activation
2. Right chest decompression with finger thoracostomy
3. RSI using a reduced dose of ketamine

The team should perform regular airway and neurologic evaluations to monitor for clinical deterioration that may warrant more rapid airway intervention. Following finger thoracostomy, the patient's oxygen saturation improves to 95%. Two units of uncrossed packed red blood cells (PRBCs) are administered, HR decreases to 80 bpm, and BP remains 105/50 mm Hg. An uncomplicated and uneventful RSI is performed using a reduced dose of ketamine (0.5 mg/kg). There is no postintubation hypotension. The patient is given postintubation analgesia and sedation and remains hemodynamically appropriate during transport to, from, and during CT imaging. The patient is then shifted to the operating room. In contrast to rigidly following the ATLS algorithm, optimization of the patient's hemodynamic status before intubation results in a more consistent hemodynamic following intubation.

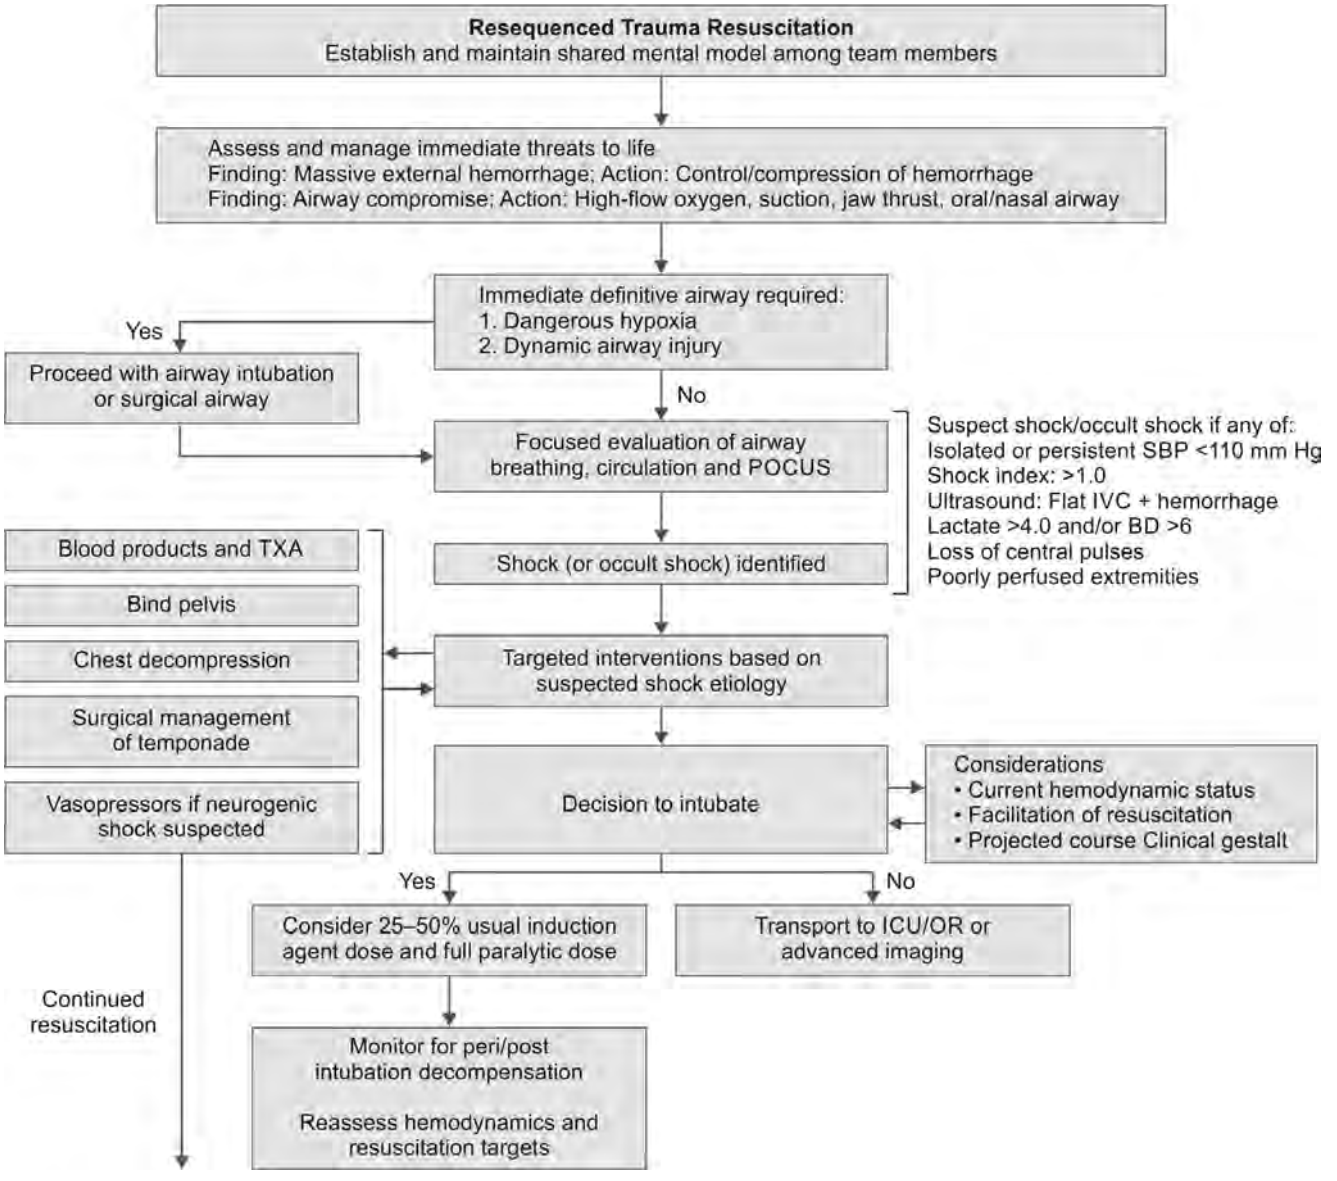
AIRWAY IN TRAUMA

Evaluation of airway remains a mainstay in the management of a trauma patient. As shown in **Flowchart 1**, the decision to intervene with a definitive airway immediately on arrival needs to be assessed by the team leader. Considerable advances in prehospital care, injury prevention, and development of trauma systems have essentially yet not been able to reduce early mortality from trauma.

A "difficult airway" is defined as difficulty in laryngoscopy, bag-mask ventilation (BMV), supraglottic devices, and/or cricothyrotomy. The "physiologically difficult airway" is defined as the nonanatomical factors that can adversely influence the outcome of airway management. Uncorrected hypoxemia, hypocapnia, hypotension, and acidosis can have devastating effects in the peri-intubation period. As a rule, all trauma patients should have their anatomical and physiological difficulties assessed, considered, planned for, and correctly executed as part of airway management plans. The airway can be managed with supportive adjuncts while an airway plan is devised and physiologic risks are assessed and addressed for postintubation hypotension and cardiovascular collapse. Intubations cause increase in intrathoracic pressure and reduced right atrial pressure.

This reversal of intrathoracic physiology has a significant impact on the shock states that are present in trauma patients. In hemorrhagic shock, an already low venous return might decline further with positive-pressure ventilation. In patients of tension pneumothorax or cardiac tamponade, the obstructive shock with reduced venous return may worsen due to positive-pressure ventilation. Focused approach to relieve obstructive causes and optimize hemodynamic in hemorrhagic shock will establish safer peri and postintubation conditions. Conditions in which immediate airway management would be required are as follows:

- *Critical hypoxemia*, even after high flow oxygen and other supportive measures



Resequenced Trauma Resuscitation
Establish and maintain shared mental model among team members
Assess and manage immediate threats to life
Finding: Massive external hemorrhage; Action: Control/compression of hemorrhage
Finding: Airway compromise; Action: High-flow oxygen, suction, jaw thrust, oral/nasal airway
Immediate definitive airway required:
1. Dangerous hypoxia
2. Dynamic airway injury
Yes
Proceed with airway intubation or surgical airway
No
Focused evaluation of airway breathing, circulation and POCUS
Suspect shock/occult shock if any of:
Isolated or persistent SBP <110 mm Hg
Shock index: >1.0
Ultrasound: Flat IVC + hemorrhage
Lactate >4.0 and/or BD >6
Loss of central pulses
Poorly perfused extremities
Shock (or occult shock) identified
Blood products and TXA
Bind pelvis
Chest decompression
Surgical management of temponade
Vasopressors if neurogenic shock suspected
Targeted interventions based on suspected shock etiology
Decision to intubate
Considerations
• Current hemodynamic status
• Facilitation of resuscitation
• Projected course Clinical gestalt
Yes
No
Consider 25–50% usual induction agent dose and full paralytic dose
Transport to ICU/OR or advanced imaging
Continued resuscitation
Monitor for peri/post intubation decompensation
Reassess hemodynamics and resuscitation targets

(BD: base deficit; ICU: intensive care unit; IVC: inferior vena cava; OR: operating room; POCUS: point-of-care ultrasound; SBP: systolic blood pressure; TXA: tranexamic acid)

FLOWCHART 1: An algorithm that focuses on intubation after resuscitation of a trauma patient has begun unless life-threatening hypoxia or dynamic airway injuries are present. It emphasizes on immediate threats to life first and subsequently on the identification and focused management of shock and occult causes of shock.

- *Dynamic airway*—blunt, penetrating, or burn injuries to the head, neck, face, oropharynx that may compromise oxygenation, ventilation, or airway management

These conditions (requiring immediate definitive airways on arrival to the ED) are a small percentage of patients with trauma. Even when the airway is a priority, concurrent management of the shock states should be established. Most patients benefit from aggressive resuscitation before intubations. Interventions include that:

- Achieve hemostasis
- Relieve obstructions
- Optimize perfusions

Once these interventions are completed (time taken will largely depend on the size and training of the trauma team), one should proceed with definitive airway management.

RECOGNITION OF SHOCK, OCCULT SHOCK, AND BLEEDING PATIENT

Shock is a clinical state defined by circulatory failure resulting in insufficient cellular oxygen use, and manifests with clinical and hemodynamic derangements. Homeostasis with peripheral vasoconstriction preserves BP as circulating volume is progressively lost. This potentially leads to inadequate cardiac output for organ perfusion even though BP remains within the normal range. Thus, in trauma patients, it is important to note that adequate cardiac output cannot be inferred from BP in isolation. Only when the blood loss has reached a critical stage, or is rapid, is there a relationship between the two. Patients with overt hypovolemic shock characterized by hypotension, tachycardia, and overt blood loss are easily and readily

identified. But trauma patients may be shocked despite normal BP and pulse, termed cryptic or occult shock; this is when we lose patients and is associated with increased mortality.

Multiple strategies have been proposed using biomarkers [lactate, base deficit (BD)], vital signs (BP, HR), or SI, each of which has specific benefits and limitations for the early identification of occult shock. Early shock identification is critical in order to prevent clinical deterioration and refractory shock states. Early identification of shock in patients with trauma can be a challenging task, especially in the presence of occult shock. Variable pathophysiologic and compensatory mechanisms produce a range of hemodynamic presentations that complicate assessment. During the initial resuscitation period, the indices for shock identification can be organized into two broad categories: (1) Clinical indicators; and (2) Laboratory indicators.

Clinical Indicators: Obtained Exclusively at the Bedside

Vital Signs

Vital signs should be obtained immediately on patient arrival and repeated frequently. Trends in vital signs are often more informative than a single, static measurement. Prehospital vital signs should be informed to the ED before arrival. This will help prepare the trauma team to manage the patient in a more streamlined fashion. Despite their limitations, vital signs are still a central element of the trauma primary survey.

Shock Index

The SI is a simple ratio of HR and can be easily calculated in the field and in the ED. HR divided by the SBP is defined as shock index. A value of 0.7 represents normal SI, whereas SI of >1.0 is highly indicative of hemodynamic instability and mortality. The SI is useful because of its simplicity, strong inter-rater reliability, and accuracy as a predictor of blood loss in trauma patients. SI should be calculated for all patients of trauma. If SI ≥ 1.0, discuss concerns regarding shock with your team. Look for any signs of occult bleeding or obstructive cause. Give TXA and blood products if SI ≥ 1.0 and hemorrhage are suspected. Studies have shown that prehospital SI ≥ 0.9 increases the chances of massive transfusion in trauma patients. Note should be made that SI can be unreliable in:

- Geriatric age groups who might have altered physiologic parameters
- Presence of underlying medical conditions such as untreated hypertension
- Medication-related disturbances (beta-blockers)

Ultrasonography

The FAST is a routine for all trauma patients. The presence of free fluid in the abdomen guides the clinician toward intra-abdominal injuries as a source of hemorrhagic shock. The extended FAST (eFAST) includes an evaluation of thoracic structures for pneumothorax and hemothorax. Evidences show that eFAST is superior to supine chest radiograph [chest X-ray (CXR)] for detecting pneumothorax. Wilkerson et al. demonstrated that compared to supine CXR, emergency physician (EP)-performed eFAST has superior sensitivity (86–98% vs. 28–75%) and equal specificity (98–100% vs. 100%). All trauma patients should undergo FAST and eFAST examinations for all trauma patients.

Laboratory Indicators: Additional Laboratory Testing Required

Base Deficit

The BD is defined as the number of base units required to return the pH of whole blood to 7.4, assuming a normal pCO_2. BD has a close correlation with transfusion requirements, injury severity, and mortality in trauma patients. The higher the BD, the more likely is the patient to receive massive transfusions and more likely to die. It is particularly valuable during the initial phases of resuscitation, because an increased BD can help identify patients who will decompensate. In severely injured patients with prehospital hypotension who are normotensive in the ED, a BD of >6 was predictive of both recurrent hypotension and death (five-fold mortality increase) compared with those with a BD < 6. A BD > 6 detected patients with transient hypotension who were likely to crump (a term used to describe acute and unexpected physiologic deterioration) again. BD > 6 is a useful tool for prognostication and to guide trauma clinicians in the resuscitation of patients.

Lactate

Initial serum lactate levels may be used as an indicator for prognosis and mortality of the trauma patient. Studies have shown conflicting conclusions. Gale and colleagues concluded that the initial lactate level is a superior prognostic marker for in-hospital mortality. Freitas et al. concluded that there was no correlation between admission lactate and mortality in trauma patients. Caputo and colleagues found that lactate and BD had similar test characteristics for predicting shock, defined as the need for operative intervention or massive transfusion. Given all the evidence, it is imperative for the EP to realize that derangement in lactates and BD > 6 should initiate the search for occult shock if not otherwise obvious.

International Normalized Ratio and Viscoelastic Assays

On arrival in the ED, 25–30% of severely injured patients are coagulopathic and fail to form adequate clots in response to hemorrhage. This early trauma coagulopathy [acute coagulopathy of trauma and shock (ACoTS)] is associated with a 4-fold increase in mortality and high rates of organ failure, highlighting the importance of early identification. Initial abnormal coagulation markers such as prothrombin time (PT), international normalized ratio (INR), and activated partial thromboplastin time (aPTT) have been linked to higher mortality rates in trauma patients. A deranged INR has also been shown to be a good predictor of mortality in trauma patients with a high diagnostic accuracy.

Two point-of-care viscoelastic assays have emerged as promising alternatives for early coagulopathy detection in trauma: Thromboelastography (TEG) and rotational thromboelastometry (ROTEM). These assays have not been extensively studied yet but are still recommended in the European

trauma guidelines. For decades, ED physicians have been applying the ATLS shock classification to predict the amount of blood loss—a system comprising four shock classes using vital signs and mental status. The global application of this classification occurred without formal study, evidence, or validation. Recently, the accuracy of these classifications has been called into question.

Trauma files from 1989 to 2007 of the United Kingdom Trauma Registry when audited demonstrated that patients progressing to stage 4 shock (>2 L of blood loss) increased HR from 82 to 95 bpm, while showing no significant changes in GCS, RR, or SBP. The ATLS shock categories are also inaccurate in geriatric patients with trauma and do not account for other causes of shock (obstructive, neurogenic) or mixed shock causes. There is no single indicator that can reliably predict shock or mortality in trauma patients. It is suggested that a combination of the indicators is used by the clinician to come up with a management plan for the trauma patient in shock.

DAMAGE CONTROL RESUSCITATION

The most dynamic and dramatic changes have occurred in the management of the actively bleeding patient. The spectrum has shifted from giving crystalloid boluses to blood product resuscitation. DCR strategies are the measures that directly address TIC. The key elements of DCR are:

- Hemostatic resuscitation
- Permissive hypotension
- Damage control surgery

Hemostatic Resuscitation

The most effective resuscitation fluid in trauma patients is their own blood. Minimizing blood loss and preserving the circulating blood volume are of utmost importance. Techniques include minimal handling, direct pressure on wounds, early closed reduction and immobilization of fractures, hemostatic drugs and blood products, and surgical or radiological interventions for hemorrhage control. Hemostatic resuscitation has two main aims: (1) Arrest hemorrhage; and (2) Prevention and correction of TIC.

Arresting Hemorrhage

Arresting bleeding and restoring blood volume are recognized as the most important step in the management of the severe trauma patient. External hemorrhage can be compressed by applying direct pressure to the site or using tourniquets. There are certain anatomic regions (groin, axilla, neck) that prove difficult for standard tourniquet use. Junctional tourniquets (for injuries in the inguinal and axillary regions) and hemostatic dressings have been developed to control proximal bleeding. A systematic review in healthy volunteers demonstrated the ability to occlude blood flow using four different junctional tourniquets with acceptable effectiveness. Although studies in trauma patient are lacking. Hemostatic dressings which can be applied directly over the wound have been evolving since 2003. These dressings have been used extensively in combat and war zones, but civilian data are still lacking. Nonetheless, using these dressings for hemorrhaging patients would not harm.

Prevention and Correction of Trauma-induced Coagulopathy

Tranexamic acid: The CRASH-2 (Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage-2) trial along with other civilian and military studies has shown that TXA administration in trauma patients reduces mortality. It is the only antifibrinolytic of choice for trauma patients across the world. TXA should be given at the earliest and has also shown to reduce head injury-related deaths. Empirically, TXA has been recommended to be given to all patients with severe trauma and in shock. In combat studies, empiric use of TXA has shown the greatest benefit in patients who subsequently required a massive transfusion. TIC is driven by shock, so we recommend to administer TXA to all trauma patients in shock or who are likely to develop shock.

Prevention of Resuscitation Coagulopathy

Resuscitation coagulopathy or acute coagulopathy of resuscitation (ACOR) is mitigated by transfusing balanced blood products (and not crystalloids which lead to dilution and TIC) using a regimen that approaches whole blood. This implies transfusing equal ratios of packed red cells, platelets, and plasma. It has been shown that a 1:1:1 transfusion ratio of platelets, plasma, and packed red cells achieved hemostasis in more patients and had lower deaths due to exsanguination than a 1:1:2 transfusion regimen. Data from multiple studies show that blood component transfusion in massive trauma reduced mortality and improved outcomes.

To minimize the development of a dilutional coagulopathy or ACOR, DCR principles advocate for the minimal (or none) use of crystalloids and the use of plasma, red blood cells (RBCs), and platelets in a 1:1:1 ratio for patients at high risk of death secondary to hemorrhage from traumatic injuries.

Massive Transfusion Protocols

The MTPs are central to DCR and designed to specifically target TIC. Protocolized transfusion avoids dilutional coagulopathy through the empiric provision of RBCs with simultaneous, high-dose clotting products (plasma, cryoprecipitate or fibrinogen concentrate, and platelets). To enable rapid delivery of a 1:1:1 strategy, MTPs are activated based on physiology and suspected active hemorrhage rather than on the diagnosis of coagulopathy. The development of a MTP for patients with severe life-threatening bleeding is important to standardize the approach to such patients and to provide structure, organization, and calmness to what is usually a tumultuous situation. Cotton et al. have studied the clinical effect of the implementation of a standardized MTP compared to historical controls and have documented improved survival and decreased organ failure. Volume resuscitation with RBCs and clotting products from the time of arrival of the severely injured patient avoid the unnecessary use of crystalloids, with blood banks providing a continuous supply of "transfusion packs" until hemorrhage control is achieved through damage control surgery or interventional radiology.

Fibrinogen Therapy

The US Military retrospective review has determined that fibrinogen transfusion had better outcomes and reduces death due to hemorrhage. If fibrinogen replacement is incorporated into MTPs, it is usually relatively late in the transfusion sequence and at a relatively low dose. Some studies have shown that fibrinogen concentrates can be administered rapidly to bleeding trauma patients in both in-hospital and prehospital environments with improvements in functional fibrinogen and plasma fibrinogen levels, while other studies are ongoing.

Calcium

Calcium is a cofactor in the procoagulant clotting proteases. Its levels rapidly fall during massive bleeding. Low ionized calcium has been associated with increased mortality and greater transfusion requirements. Levels should be checked regularly during resuscitation and replaced to maintain levels within the normal range.

Rewarming

In DCR, hypothermia should be managed in conjunction with the efforts to correct the trauma-induced coagulopathy. It is essential to rewarm the torso using passive warming measures, such as insulating foil, blankets, and removal of wet clothes. Hypothermia in trauma can lead to worsening of acidosis and in turn worsen TIC and increase mortality. TIC is multifactorial, with varying degrees of dysfibrinogenemia, hyperfibrinolysis, endothelial dysfunction, and impaired platelet activity. Although most coagulation therapy is empiric, it is of utmost importance to monitor coagulation status to ensure that a hemostatic state is maintained. Point-of-care coagulation monitoring may allow for a more focused approach to the management of TIC during DCR. Early endogenous processes that trigger the adverse response in the coagulation system depend on the severity of trauma and the level of hemorrhagic shock. DCR and the use of MTPs are associated with improved outcomes in TIC.

Permissive Hypotension

Normalization of BP should not be the goal during trauma resuscitation at any point of time. The use of permissive hypotension as a strategy to minimize active bleeding was established in the nineties for ruptured abdominal aneurysms. Permissive hypotension or hypotensive resuscitation, in other words, strategizes the use of limited or no fluids and blood products to maintain a lower than normal BP unless the bleeding has been controlled surgically or radiologically. The aim is to avoid "*popping the clot*" while still maintaining oxygen perfusion to all tissues. Permissive hypotension is by far the most difficult concept to understand and implement as part of the DCR strategies. Giving fluid infusions will cause dilutional coagulopathy, anemia, endothelial damage, and tissue edema, all of which are associated with poor outcomes. High-volume fluid resuscitation causes an increase in trauma-related bleeding, multiorgan failure, and death.

A mean arterial pressure (MAP) of 65 mm Hg should be targeted during hypotensive resuscitation in the trauma patient. One has to be sure that there are no TBIs and the patient is perfusing well at this MAP. If MAP increases beyond 65 mm Hg, one can give fentanyl in 25–50 μg aliquots to bring it down. If it drops below 65 mm Hg, then blood products can be given to bring it to target.

The place of vasopressors in early trauma resuscitation is still controversial. We can maintain BPs above coronary artery perfusion pressure with blood products and early surgical intervention, where required. Permissive hypotension in TBI is still controversial. Hemorrhaging patients with TBI usually have a poorer outcome than those who do not suffer from TBI. Experimental studies have shown that in the setting of hemorrhage and TBI combined, aggressive fluid resuscitation and higher BP targets led to increased cerebral edema, increased intracranial pressures, and mortality. The National Institute for Clinical Excellence (NICE) major trauma guideline suggests that the clinician should focus resuscitation on the predominant injury complex, so a restrictive fluid administration is advocated where bleeding is the dominant pathology being treated. They suggest to use a less restrictive strategy if TBI is the dominant component in the trauma patient to maintain cerebral perfusion.

Permissive hypotension is now an integral part of the DCR strategy in trauma centers throughout the world. One needs to understand that it is a temporizing measure until full hemorrhage control has been achieved by surgery. It is important to realize that hemorrhage control is the goal and not normalization of the BP.

Damage Control Surgery

This is the final cog in the wheel of DCR. Post resuscitation of the trauma patient using all the above techniques, the patient needs to be wheeled for surgery for definite hemorrhage control. Till now, the aim of trauma management in the ED was to ensure that the patient stays alive using the best possible methods and techniques and also does not succumb during or post surgery. Abdominal injuries' damage control entails rapid celiotomy, control of hemorrhage, minimizing contamination, and temporary abdominal closure. Surgical bleeding may be controlled by a combination of packing, clamping, and ligation. Splenectomy and nephrectomy may also be required. Thoracic injuries are more challenging as it is very difficult to achieve hemostasis in these patients. Rapid and definitive control of hemorrhage is required. Pulmonary tractotomy can accomplish rapid control of bleeding in penetrating lung injuries. Vascular injuries can be temporarily controlled by simpler techniques such as ligation, lateral repairs, and temporary shunts. Once coagulopathies are corrected and physiology is normalized, more complex procedures such as vascular reconstructions and patch angioplasties can be undertaken. The critical component of head injury management is the prevention of secondary brain injury.

It is important for trauma providers to be updated regarding DCR strategies as they are clearly lifesaving in many polytrauma patients. The concept has been upgraded and modified over many years, and it is clear that there will be a constant change in guidelines. As trauma is so dynamic, the guidelines will have to be dynamic too.

SUMMARY

The identification and resuscitation of the shocked patients with trauma is a complex and dynamic condition. The traditional rigid approach advocated by ATLS can at times lead

to ineffective prioritization of critical injuries in favor of less urgent interventions. This chapter proposed the application of evidence-based techniques for shock identification combined with trauma resuscitation guided by physiologic priorities. A newer approach in trauma resuscitation represents a unique and important cultural shift in trauma care. It emphasizes upon physiologic optimization before intubation. This "resequenced" approach first addresses immediate threats to life followed by targeted treatment strategies for the diagnosis and management of shock causes. It is both practical and feasible across the varied spectrum of settings in which trauma care is provided across the globe. Some salient points to remember in trauma resuscitation are provided in **Box 1**. Improved resuscitation strategies will inevitably optimize outcomes for patients with trauma. As mentioned before, trauma resuscitation is dynamic and undergoing continuous research. It is recommended for all emergency medicine physicians to stay updated with what is vogue in trauma.

BOX 1: Important points to remember while managing the critically injured.

- Unless critical hypoxia or dynamic airway, defer definitive airway (provide temporizing measures)
- Look for occult shock
- Manage immediate threats to life
- Use clinical and laboratory values—shock index, lactates, base deficit, FAST
- Use tranexamic acid early
- Use the 1:1:1 transfusion protocol of FFP, platelets, and packed red cells
- Permissive hypotension in bleeding patient, avoid crystalloid transfusions
- Reduce dose of induction agent to half in the shocked patient. Normal dose of paralytic

(FAST: focused abdominal sonography in trauma; FFP: fresh frozen plasma)

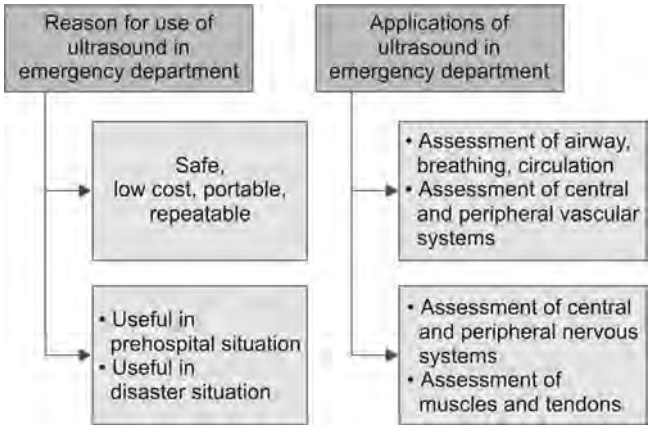
CHAPTER

Focused Assessment with Sonography in Trauma

Devendra Richhariya

INTRODUCTION

Traumatic injury remains the leading cause of death in all age groups and result in a substantial proportion of patients with injuries from blunt abdominal and/or chest trauma treated in emergency departments. Three decades ago, the advent of focused assessment with sonography in trauma (FAST) enabled the clinicians to rapidly screen for injury at the bedside of patients, especially in hemodynamically unstable patients who are not suitable for transfer to the computed tomography (CT) suite. The identification of free fluid within the peritoneal cavity, pericardium, and pleural spaces can be accomplished immediately at patient arrival to the hospital. Usefulness of FAST starts with prehospital transport and multiple casualty settings as a triage tool and further extends toward detection of solid-organ injury, pneumothorax, fractures, and serial examinations. As a radiologist relies more on CT than ultrasound (US) in cases of trauma, use of FAST has migrated to first responders or the emergency physician. In the emergency department, FAST is also typically used as the patient's initial imaging examination at arrival. There are quite a few reasons behind usefulness of ultrasonography (USG) in the emergency department, e.g., safety, low cost, portable, repeatable (**Flowchart 1**). Since the original description of the use of USG in a trauma patient is well known, several new applications of the use of USG in trauma patients have also been described.



Reason for use of ultrasound in emergency department
Applications of ultrasound in emergency department
Safe, low cost, portable, repeatable
• Useful in prehospital situation
• Useful in disaster situation
• Assessment of airway, breathing, circulation
• Assessment of central and peripheral vascular systems
• Assessment of central and peripheral nervous systems
• Assessment of muscles and tendons

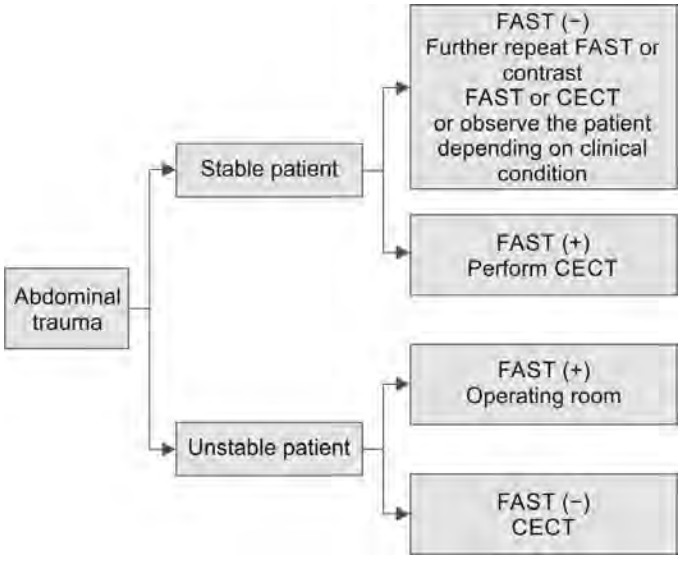
FLOWCHART 1: Usefulness of ultrasound in the emergency department.

EVOLUTION OF FAST

For the examination of trauma patients, USG was first utilized in the 1970s in Europe but until 1990s it was not utilized widely, during which time the FAST acronym was pronounced as "focused abdominal sonography for trauma." Over time, USG was used for more comprehensive examination; hence, the FAST acronym was changed to "focused assessment with sonography for trauma." Since then, FAST has become the common initial screening modality in the majority of trauma centers worldwide, and it is also included in the advanced trauma life support (ATLS) program for evaluation of the trauma patient. A unique aspect of FAST is that, with variable training and experience, it can be routinely utilized by radiologists, emergency physicians, and surgeons.

ACCURACY OF FAST AND CLINICAL DECISION-MAKING

Studies were published regarding sensitivity and specificity for detecting hemoperitoneum which were 80% (Asher and colleagues in 1978) and 70–98% (various studies in the 1990s), respectively. Initially, the outcome was measured and compared with the patient's outcome and not with CT scan, so sensitivity was reported high in studies which were done in the early 1990s. One of the first studies that compared FAST to CT scan showed a lower sensitivity of 65% for FAST in detecting solid-organ injuries. The low sensitivity is due to detection of an isolated solid injury by CT scan without hemoperitoneum. Carter et al. reported a sensitivity of 22% in a retrospective study of 1,671 blunt abdominal trauma patients (25 of 114) in hemodynamically stable patients and 28% (nine of 32) in unstable patients, and they concluded that an intra-abdominal injury may be missed if a negative FAST study was not followed up with further CT scan. It is now well recognized that intra-abdominal injuries may remain underdiagnosed with FAST, so in cases of negative FAST further diagnostic testing with a CT scan of abdomen should be taken on the



(CECT: contrast-enhanced computed tomography; FAST: focused assessment with sonography in trauma)

FLOWCHART 2: Diagnostic algorithm for the use of FAST for triaging of a trauma patient.

basis of clinical suspicion, mechanism of injury, and change in clinical examination or hemodynamic status (**Flowchart 2**). For patients with a negative FAST study, observation, serial FAST, CT scan, or contrast material—enhanced USG may be chosen. Use of FAST in the evaluation of unstable, hypotensive trauma patients is also recommended. The most effective use of FAST has been rapid triage of hemodynamically unstable trauma patients to definitive intervention, leading to reduced time to appropriate intervention, shortened hospital stays, and lower costs. The need for diagnostic peritoneal lavage (DPL) is also shown to reduce with the FAST examination with one prospective study of 194 patients reporting a reduction from 9 (17 of 194) to 1% (two of 194).

FIG. 2: Fluid in Morison pouch.

FAST TECHNIQUE AND INTERPRETATION

In the evaluation of the trauma patient, probe selection is dependent on what is the main focus of the examination. A multipurpose probe (3–5-MHz sector probe) is best utilized and appropriate for examining solid organs as well as for determining the presence of free fluid in the abdomen or pelvis (**Fig. 1**). A sector scanner can be used to examine the heart for a pericardial effusion or hemorrhage and is also useful to scan between the ribs for pneumothorax. A curved-array transducer is used for better visualization of the abdomen but for imaging of the heart or lung, a curved-array transducer is not ideal, especially when scanning in the intercostal spaces. For detection of pneumothorax, the linear-array transducer probe is placed parallel to the ribs in the intercostal space. The original FAST scan included views of (1) The right upper quadrant, which included the perihepatic area and hepatorenal recess or Morison pouch (**Fig. 2**); (2) The left upper quadrant, encompassing the perisplenic view; (3) The suprapubic view (pouch of Douglas) (**Fig. 3**); and later (4) A subxiphoid pericardial view. The first site which should be scanned for

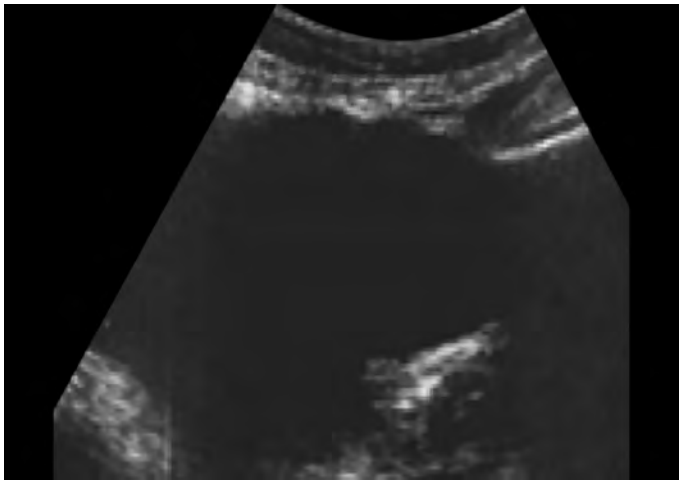

FIG. 3: Fluid in the pouch of Douglas.

detection of free fluid with FAST is the right upper quadrant by using a lower frequency (3.5–5 MHz) sector or curved-array transducer. For examining the hepatorenal fossa or deep pelvis, a sector transducer with far-field optimization is ideal for best visualization. For optimized and deep penetration, a curved-array transducer may also be used. The liver serves as a convenient acoustic window to examine the hepatorenal space and liver parenchyma. As compared with adjacent solid organs, the hemoperitoneum usually appears anechoic or hypoechoic. Prolonged hemorrhage may organize and visualize as more echogenic.

The left upper quadrant view is scanned next and the spleen is targeted for examination in the splenorenal fossa and perisplenic area. Visualization of the left pleural space is performed by cephalad scanning. The probe is moved caudally to visualize the inferior pole of the left kidney and paracolic gutter. Due to difficult physical access, the perisplenic area may be difficult to scan; this may be overcome by rolling the patient to the right side, as small amounts of free fluid may collect superiorly to the spleen.

The suprapubic view allows assessment of the peritoneal cavity which is the most dependent space of the abdomen. The transducer should be placed above the pubic symphysis in a sagittal plane and moved side to side and then rotated transversely and repeatedly. The chances of detection of free fluid in the pelvis are more in reverse Trendelenburg positioning. Small amounts of free fluid of up to 50 mL in the pouch of Douglas are considered physiologic in female patients of reproductive age, and amounts >50 mL should be regarded as pathologic in the setting of trauma. Free fluid should not be found at the rectovesicular space in men, assuming that there is no injury or other pathologic conditions.

Limitations

Regardless of the protocol used, there are limitations to the FAST examination because blunt (mesenteric, bowel, diaphragmatic, and retroperitoneal) as well as isolated penetrating injury to the peritoneum can be difficult to detect during the abdominal examination. False-positive scans may occur due to the presence of ascites, peritoneal dialysate, ventriculoperitoneal shunt outflow, ovarian hyperstimulation, and ovarian cyst rupture. False positive FAST examination may also be evident after large volume fluid resuscitation; transudation of fluid from intravascular area to intraperitoneal area. Although in trauma patients, free fluid detected with FAST is assumed to be hemoperitoneum, it can also be trauma-related urine, bile, and bowel contents. Common obstacles to USG visualization are bowel gas, subcutaneous emphysema, and obesity. Patients who present late after trauma or hemoperitoneum (contain clots) may be missed on FAST due to mixed echogenicity. Perinephric fat may be misinterpreted as free fluid or subcapsular hematoma due to widening of the hepatorenal and splenorenal interface, also known as the "double-line" sign. In these cases, compare the views of each kidney. The certain amount of volume of free fluid necessary to be detected by FAST is the limitation. Visualization of free fluid in the splenorenal and hepatorenal interface can be improved by the Trendelenburg position.

NEWER PROTOCOLS AND EXTENDED FAST

Evaluation of the thorax is also added later on in the traditional FAST examination to detect pneumothorax , thus resulting in extended focused assessment with sonography in trauma (eFAST). The protocol for evaluation of shock, respiratory distress, and cardiac arrest is also added, e.g., protocol for evaluation of dyspnea: BLUE (bedside lung USG in emergency) and RADIUS (rapid assessment of dyspnea with USG). The BLUE protocol includes only lung USG for detection of pneumothoraces as well as pulmonary edema, consolidation, and effusion. The RADIUS protocol is similar to BLUE but also includes evaluation of cardiac and inferior vena cava (IVC).

The RUSH (rapid USG for shock and hypotension) protocol was simplified and described as an examination of the (1) pump, (2) tank, and (3) pipes for better understanding. The "pump" evaluation includes parasternal long and short axes of the heart plus subxiphoid and apical views. The "tank" evaluation involves interrogation of the IVC, FAST examination of the abdomen including pleural views, and US of the lung. The "pipes" portion of RUSH involves visualization of the suprasternal, parasternal, epigastric, and supraumbilical aorta, with additional scans of the femoral and popliteal veins for deep venous thrombosis. The RUSH examination is not specifically for trauma patients; thus the "pipes" portion of the protocol is usually not necessary in the setting of acute trauma.

The number of different protocols for evaluation of the critically injured is a source of confusion. The most practical and time efficient of these protocols are the eFAST examination, which includes evaluation for pneumothorax, and portions of the RUSH examination, which include a brief subcostal view of the heart and evaluation of the IVC (**Fig. 4**). The selective use of eFAST and RUSH specifically for the setting of trauma is discussed below:

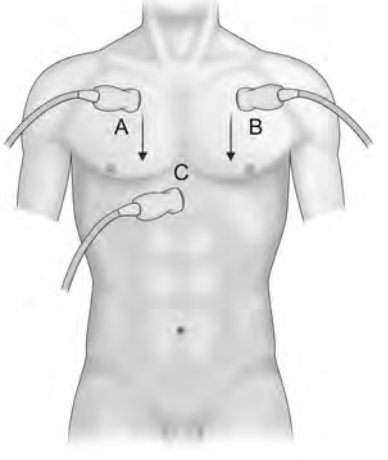

FIG. 4: Additional views that may be helpful in the trauma patient: A = right parasagittal view of the lung for pneumothorax, B = left parasagittal view of the lung for pneumothorax, C = a longitudinal view of the inferior vena cava.

HEART

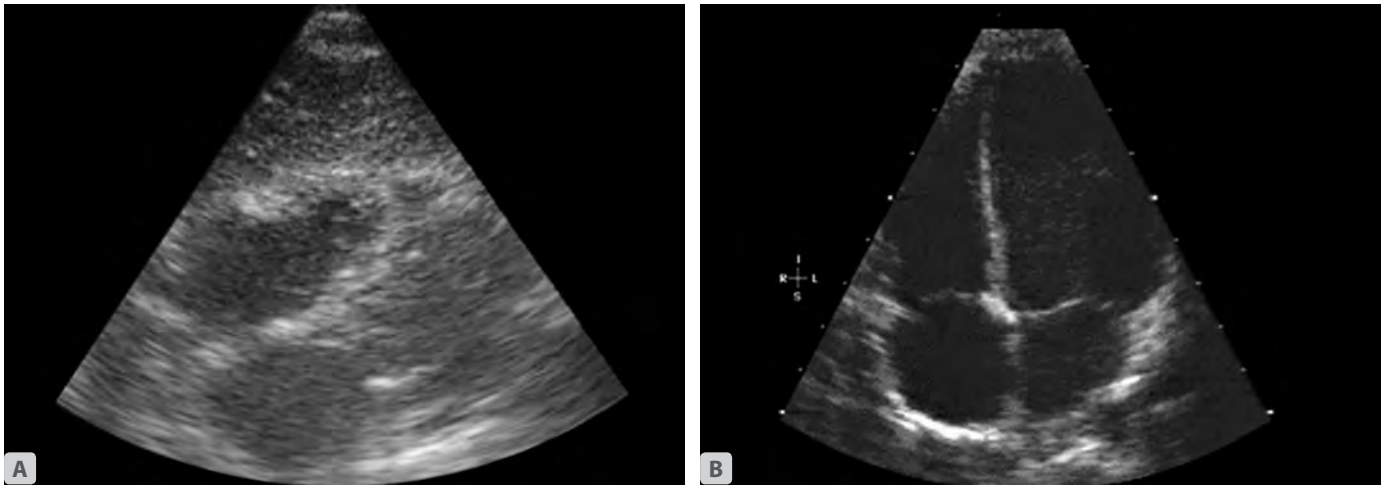
Subxiphoid images of the heart are visualized by keeping the transducer on the upper abdomen and pointing superiorly toward the left shoulder. The volume status of heart can be visualized and assessed (**Figs. 5A** and **B**). Fluid surrounding the heart is seen as an anechoic space surrounding the myocardium and/or ventricle (**Fig. 6**). The liver aids as an acoustic window. If there is difficulty in obtaining the subxiphoid view, parasternal, apical four chamber, and subcostal approach may be attempted. If a substantial amount of hemopericardium is detected, with diastolic collapse of the right atrium, cardiac tamponade is most likely present. Differentiation between fluid in the posterior pericardial space and fluid in the posteromedial pleural cavity may be difficult to distinguish from each other. For differentiation of the two, visualize the descending thoracic aorta, as pericardial fluid is present anterior to the aorta whereas pleural fluid is present posterior to the aorta. Pericardial cyst, fat pad, and preexisting effusion may give false-positive results for hemopericardium. The subxiphoid pericardial area may be inadequately scanned due to a suboptimal acoustic window but can overcome these limitations by increasing the depth for this view or by performing a left parasternal longitudinal scan for pericardial fluid.

HEMOTHORAX OR PLEURAL EFFUSION

The right pleural space is visualized for free fluid as well as for the area between the dome of the liver and diaphragm. This area appears as an echogenic curvilinear line, and echoes similar to liver parenchyma can be seen superiorly. This mirror image is suggestive of the absence of pleural fluid. During normal lung inspiration, this mirror image may seem distorted intermittently, referred to as the "curtain sign." Based on the composition of pleural fluid (e.g., hemorrhage, exudate, transudate, empyema), images may be anechoic or have mixed echogenicity and atelectatic lung can also be visualized with pleural effusion (**Fig. 7**). Detection of pleural fluid can be improved by upright or reverse Trendelenburg positioning.

PNEUMOTHORAX

There are fewer studies evaluating the accuracy of eFAST (relatively a new protocol) in detecting pneumothorax. The diagnosis of small-to-moderate-sized pneumothoraces



FIGS. 5A AND B: (A) Hypovolemic cardiac chamber; (B) Normovolemic cardiac chambers.

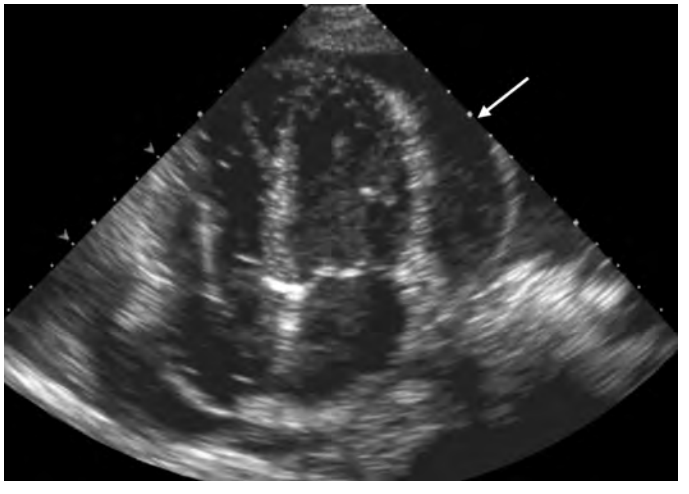


FIG. 6: Pericardial effusion: Four-chamber view of the heart demonstrates moderate-sized pericardial effusion.

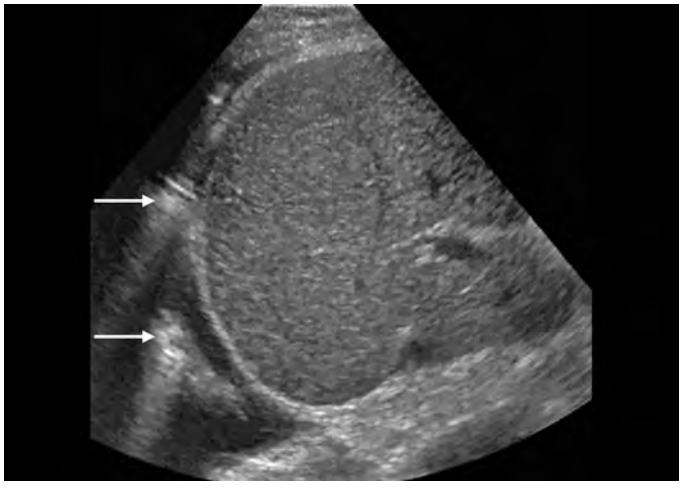

FIG. 7: Pleural effusion and atelectasis. Scan through the liver shows free fluid in the thorax that surrounds the more echogenic lung.

with physical examination and supine chest radiography is challenging, and these occult injuries may be missed in blunt trauma patients. The sensitivity of eFAST is found better than that of supine chest radiography in studies using CT as the reference standard. Kirkpatrick and colleagues performed a prospective blinded study with eFAST in trauma patients and reported a sensitivity of 48.8% for chest USG versus 20.9% for chest radiography. Lanniello and coworkers investigated unstable trauma patients with eFAST and reported a sensitivity of 77% for detection of pneumothorax.

A high-frequency (5-MHz) linear transducer probe is preferred for detection of pneumothorax, but lower frequency sector transducers and even a curved transducer may also be used. The transducer is placed in the second or third intercostal space in the midclavicular line in sagittal orientation and then moved inferiorly (**Fig. 4**). To obtain a larger view of the lung, the probe can also be placed in an oblique fashion between the ribs. Compare the findings of both side of lung, by placing the probe on different positions of anterior chest and also opposite side of the chest. Normal lung can be demonstrated by visualizing the *"sliding lung" sign*, a most helpful USG finding (**Figs. 8A** and **B**). In normal lung, the visceral and parietal pleural interface is always visualized on USG as an echogenic line and the visceral pleura is moved over the parietal pleura (fixed part) giving rise to the *"sliding lung" sign*. If the sliding lung is seen, it excludes pneumothorax at that site. Absence of the normal sliding lung is highly suggestive of pneumothorax but may also be seen in other pathologic conditions where there is no lung movement such as apnea, atelectasis, chronic obstructive pulmonary disease (COPD), bulla formation, pleural thickening, and postpleurodesis. Subcutaneous emphysema can obstruct the visualization of the underlying pleural cavity and is frequently associated with pneumothorax. The severity of illness may also be a factor for absence of lung sliding for detecting pneumothorax in critically ill patients with respiratory failure.

Other findings observed in lung USG are so-called A-lines seen with normal lung, but these are both normal and abnormal A-lines. Normally, A-lines are reverberation artifacts from the visceral and parietal pleura and always equally spaced, horizontal echogenic lines running parallel to the transducer, and are a predominant feature with normal lung. However, abnormal A-lines may be associated with a pneumothorax. "B-lines" are vertical lines extending from the transducer toward the edge of the screen. Both A- and B-lines can be seen in both normal and abnormal lung but with distinction. In normal lung, sliding is always present, the A-lines are perfectly spaced, and the B-lines are very small.

B-lines maybe visualized as many variants including "comet tails," which are thin vertical lines extending only a short distance from the transducer. *With pneumothorax* (1) There is absent sliding lung; (2) A-lines are present, more numerous than normal, and not evenly spaced; and (3) B-lines are no longer present (**Fig. 9**). While small B-lines that do not extend all the way through the image are seen in normal

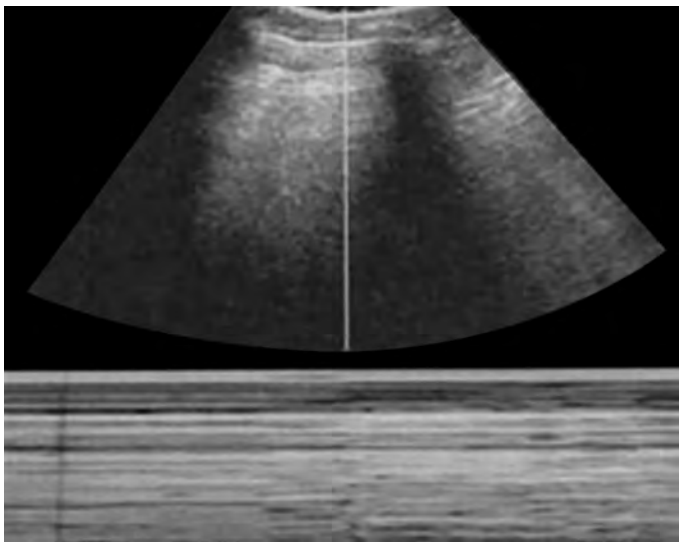

FIG. 9: Right pneumothorax and stratosphere sign with presence of multiple echogenic A-lines but lack of anterior echogenic "sliding lung" interface of parietal/visceral pleura.

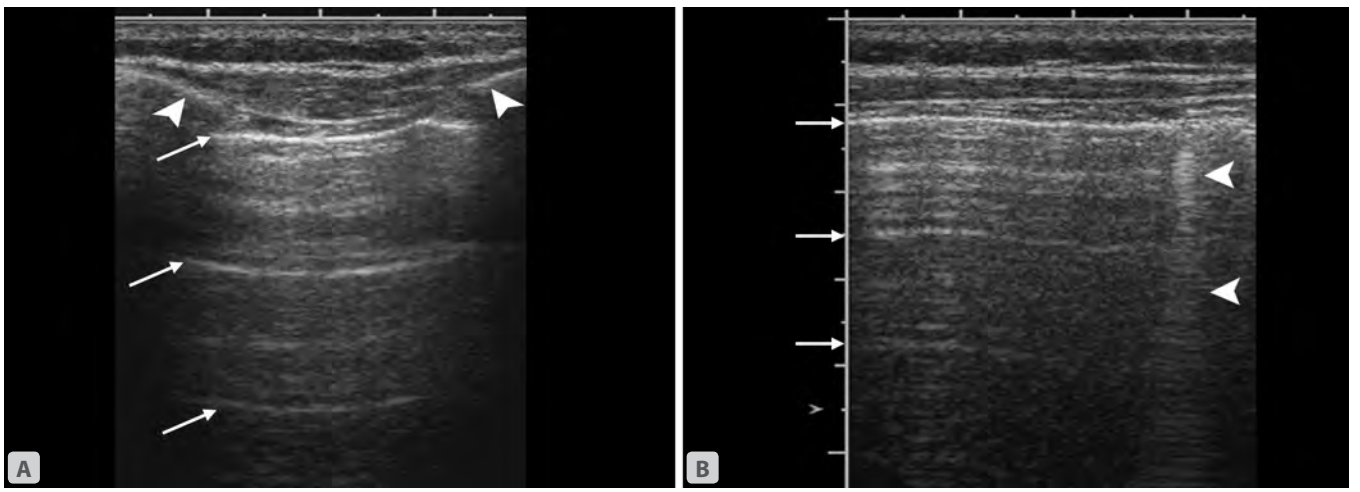


FIGS. 8A AND B: Normal lung. (A) Parasagittal view of the lung between the ribs shows shadowing at the anterior ribs (arrowheads). The most anterior echogenic line (arrow just below arrowhead) is the junction of the parietal and visceral pleura, where motion of sliding lung is observed. There are also A-lines (lower two arrows), which are equally spaced reverberation artifacts and decrease in echogenicity with depth. (B) Scan between ribs shows the most echogenic line (anterior arrow) or the junction of parietal and visceral pleura which represents the "sliding lung" sign in real time. Multiple reverberation artifacts are noted (posterior arrows). A- and B-lines or "comet tail" artifact is also seen (arrowheads).

patients, longer and more numerous B-lines are seen in patients with pneumonia or pulmonary edema.

B-lines are never associated with a pneumothorax; if present, this indicates that the lung is not moving but may be diseased. So, detection of B-lines with absent sliding lung is not diagnostic of a pneumothorax. Multiple B-lines that originate from the pleural surface and extend through the image are termed "lung rockets" which are associated with either consolidation or pulmonary edema.

Upper rib, pleural line, and lower rib on USG appear like a "bat sign," which is a normal finding. Visualization of junction between the normal and abnormal lung is termed "lung point." The lung point can be used as a reference point to estimate the size of the pneumothorax. In the M-mode of USG, a "seashore sign" is equivalent to lung sliding and absence of the "barcode sign" is considered as a pneumothorax. "Barcode sign" is also known as "stratosphere sign."

A pneumothorax can easily be detected which are directly under the probe, but smaller, apical, localized pneumothoraces may be missed. Comparison scans of the right and left chest walls may be helpful unless bilateral pneumothoraces are present. The transducer may also be used to identify rib fractures by following the length of the rib longitudinally. Normal ribs are visualized as an echogenic thin interface below the soft tissues of the chest wall with posterior acoustic shadowing. If rib fractures are present, this continuous smooth interface is disrupted. Similarly, the sternum fracture may also be visualized if suspected.

INFERIOR VENA CAVA

At many trauma centers, FAST has been extended even further to include scanning of the IVC during respiration as a noninvasive means of volume status assessment. Utility of USG in estimating right atrial pressure in healthy volunteers is first reported by Simonson and colleagues in the late 1980s. The hemorrhage is the most common cause of hypotension and hypovolemic shock in a trauma patient, but cardiogenic, neurogenic, or distributive shock may also occur due to injuries to the heart or central nervous system. USG of the IVC is helpful in differentiating the various forms of shock.

There is basic science and general correlation between the IVC diameter and the central venous pressure (CVP); thus, IVC is measured by USG and volume depletion is considered if a smaller diameter of the IVC is measured (**Figs. 10A** and **B**).

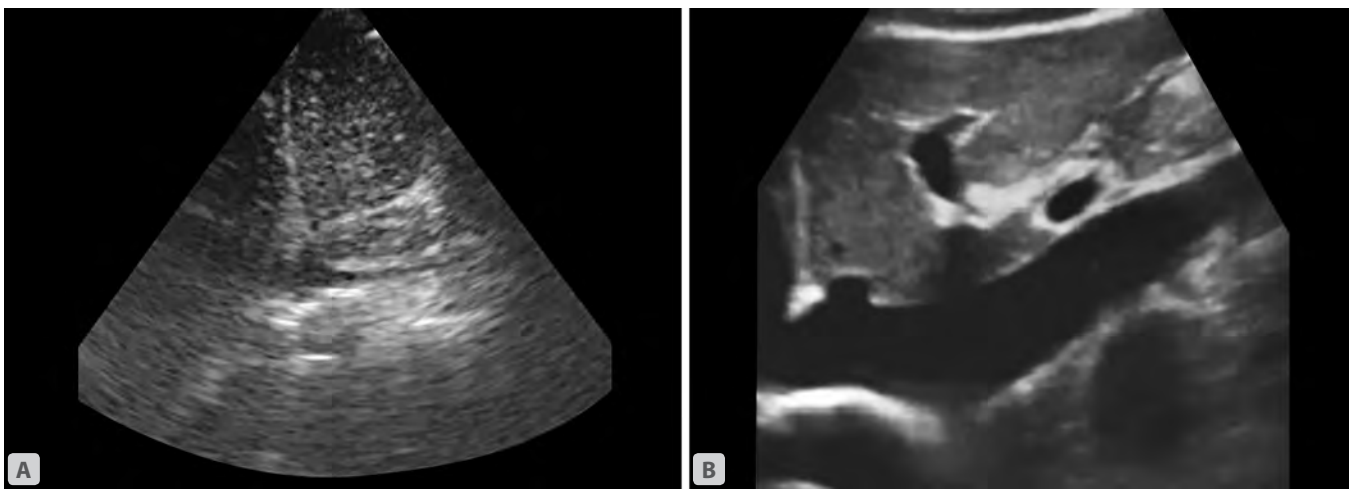
- If IVC diameter is <1.5 cm, (total collapse) estimated CVP would be 0–5 cmH_2O.
- If IVC diameter is 1.5–2.5 cm, CVP would be 6–10 cmH_2O (if >50% collapse with respiratory change) and CVP would be 11–15 cmH_2O (if <50% collapse with respiratory change).
- If IVC diameter is >2.5 cm, CVP would be 16–20 cmH_2O (if <50% collapse with respiratory change).

Ultrasonography of the IVC is visualized and measured with the patient in the supine position using the same low-frequency curvilinear transducer as for the abdominal views. A subxiphoid approach is adopted with the transducer in the sagittal position. The IVC diameter is measured 2 cm below the cavoatrial junction; at this cavoatrial junction, IVC enters the right atrium (**Fig. 11**). For comparison, both inspiratory and expiratory diameters are measured (**Fig. 12**). For more precise measurement of the IVC, M-mode is preferred. Interpretation of IVC is based on the diameter and degree of inspiratory collapse of the IVC in nonintubated patients or in intubated patients not receiving positive-pressure ventilation. The normal expiratory diameter of the IVC with a normovolemic patient is 1.5–2.5 cm and during inspiration, IVC collapses to <50% of its expiratory diameter. *The caval index is calculated as a percentage with the formula:*

Caval index: [(IVC expiratory diameter – IVC inspiratory diameter)/IVC expiratory diameter] × 100

An index approaching 100% indicates almost complete collapse and likely volume depletion whereas an index near 0% indicates minimal collapse, suggesting volume overload. Ferrada and coworkers studied 101 hypotensive acute trauma patients who underwent IVC USG and reported poor prognosis for those patients with a collapsed IVC. For trauma patients, the simplest approach is to visualize and measure the IVC to see if it has substantial collapse with a small diameter (<1.5 cm), indicating volume depletion.

For IVC US, there are diagnostic limitations for its use in the estimation of shock in intubated patients with positive-pressure ventilation, as the IVC diameter will be increased. Severe COPD, pulmonary hypertension, right-sided heart failure, cardiac tamponade, and tricuspid regurgitation may



FIGS. 10A AND B: (A) Small collapsed IVC and hypovolemia; (B) Normovolemic and expanded inferior vena cava.

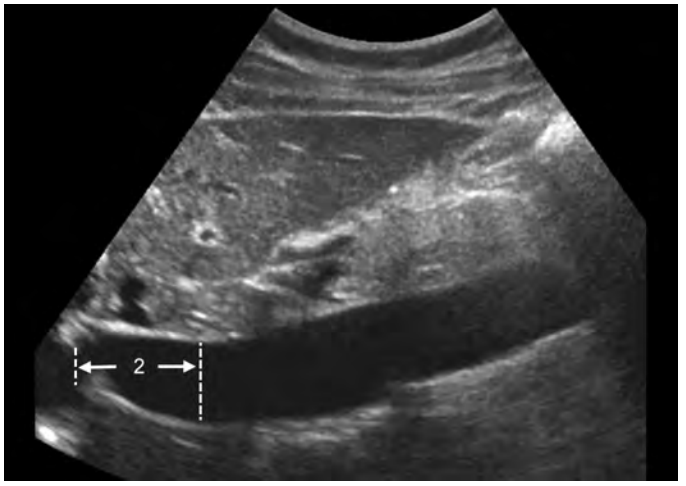


FIG. 11: Normal inferior vena cava. The inferior vena cava diameter is measured 2 cm below the cavoatrial junction (arrows) on this parasagittal view.

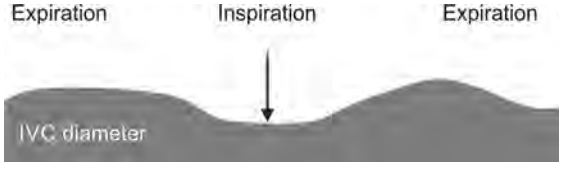

FIG. 12: Normal variation of inferior vena cava diameter with spontaneous breathing in an otherwise healthy patient. This spontaneous change may not be present in certain disease states or positive-pressure ventilation.

also increase IVC diameter and render an inaccurate estimate of shock. Additionally, the IVC can be difficult to detect in hypotensive trauma patients with hypovolemic shock owing to its reduced diameter.

SERIAL FAST

Serial FAST in stable blunt trauma patients may be useful as a sonogram represents real-time examination. A comprehensive USG examination can be performed after trauma stabilization as it gives more time to the operator. Nunes et al. reported that serial FAST examinations decreased the false-negative rate by 50% and increased sensitivity for free fluid detection from 69 to 85%. Other studies have confirmed these results. For detection of intra-abdominal injuries, a baseline CT scan, which has high sensitivity, could be supplemented by FAST performed at bedside if the patient becomes unstable. Serial FAST can be used in stable trauma patients, in patients with a sudden change in hemodynamic status or physical examination, and in pregnant trauma patients to avoid radiation exposure.

SOLID-ORGAN EVALUATION

The FAST examination was originally introduced to detect intraperitoneal free fluid. USG is also helpful in identifying injuries of solid-organ parenchyma, especially during serial FAST. A diffuse heterogeneous pattern is most commonly detected in splenic lacerations whereas a discrete hyperechoic pattern is seen most often in hepatic lacerations. Subcapsular splenic hematomas are detected as either hyperechoic or hypoechoic rims surrounding the parenchyma, and splenic lacerations tend to become hypoechoic over a few days. A USG scan for urological trauma; high grade renal injuries can be visualized as mixed echogenicity with disorganized pattern and bladder hematomas frequently appear echogenic.

BOWEL AND MESENTERIC INJURY

Immediately after a trauma, the volume of hemorrhage and/or extravasated bowel contents is usually minimal; thus, immediately after the injury, detection of bowel and mesenteric injuries with FAST is too difficult. Fluid-filled bowel loops may be confused with free intraperitoneal fluid, but bowel loops can be distinguished from free fluid with the presence of peristalsis. Additionally, pneumoperitoneum from bowel perforation can mimic air within small and large bowel loops at USG or appear as echogenic lines, bands, or spots with posterior reverberation artifacts. Free air in peritoneal cavity changes with patient position and is termed the "shifting phenomenon." The "peritoneal stripe sign" may be visualized with USG when both free fluid and air are present in the peritoneal cavity.

PREGNANT PATIENTS

Blunt and penetrating trauma is the leading cause of nonobstetric maternal mortality, affecting up to 7% of pregnancies. It is an important cause of fetal loss, and most obstetric complications from trauma occur in the third trimester. The most common mechanism of trauma is assault. USG is advantageous in pregnant trauma patients as there is no contrast material or radiation exposure to the mother or the fetus. USG is helpful in rapid assessment of the free fluid as well as in assessment of fetal activity, fetal heart monitoring, amniotic fluid volume, approximate gestational age, and placenta. Placenta examination is very important, as abruption may have a variety of appearances, such as thickened or avascular regions in the placenta without accompanying free fluid in the pelvis. Continuous cardiotocographic monitoring should be started as early as possible to screen for placental abruption in patients with negative or equivocal FAST findings. While every effort should be made to reduce radiation to the fetus, low-dose CT with contrast material (with no known teratogenic effect to the fetus) may be recommended.

FAST AND PEDIATRIC PATIENTS

Several studies of FAST done in pediatric trauma patients have shown similar sensitivities and specificities to those in adults. However, a similar number of studies have shown lower sensitivity as well. For detection of hemoperitoneum, pediatric FAST had an overall sensitivity of 66% and specificity of 95% as per one of the meta-analyses. The use of FAST has decreased the possibilities of radiation exposure from CT in pediatric trauma patients.

TRAINING AND EXPERIENCE

Limitations of USG detection of findings in traumatic chest and abdominal injury are associated with technical errors and

level of operator training. The level of training required for an "experienced" USG operator is not clearly defined and differs between organizations, sonographers, emergency physicians, and surgeons. At least 200 supervised examinations must be performed to be considered experienced according to the definition developed from the first FAST consensus conference in 1999. It was observed that the majority of errors occur in the first 10 examinations; further accuracy improves after 25–50 examinations. Jang et al. reported that inadequate gain and/or depth setting and inadequate anatomic interrogation may also give a false-negative FAST result by emergency physicians in-training.

FUTURE APPLICATIONS

As USG equipment becomes more compact and light weight, the use of FAST in the prehospital setting is becoming more popular and is ideal for rapid triage of injured patients in multiple casualty incidents or battlefield situations. After a natural disaster, an earthquake in Armenia in 1988, the use of FAST was first described by Sarkisian and coworkers. The use of USG in natural disasters has also been reported, such as earthquakes in Turkey (1999), China (2008), and Haiti (2010); floods in Guatemala (2005); and a cyclone in Australia (2007). The use of USG for detecting long bone and pelvis fractures, in mass casualty incidents, is being investigated. The role of contrast-enhanced USG for trauma is not clear yet, but it appears to be a promising method to improve detection of parenchymal organ intra-abdominal injuries. Advantages of contrast-enhanced USG include lack of ionizing radiation exposure, portability, safety, and repeatability, thus making it ideal for conservative injury management, especially in children and pregnant or fertile female patients. Potential applications of contrast-enhanced US include serial scanning of known organ injuries, follow-up imaging in patients with inconclusive CT findings, and use in patients with hypersensitivity to iodinated contrast agents.

SUMMARY

For the past three decades, FAST was extensively utilized and studied in blunt and penetrating trauma. Earlier to diagnose intra-abdominal injury, invasive procedures such as DPL and exploratory laparotomy were commonly utilized. Nowadays, FAST examination is used not only for detecting the free fluid in abdominal trauma but also for visualization and evaluation of heart, chest, and IVC, along with the use of many variations in technique, protocols, and interpretation. Trauma management strategies have also changed over the years such as laparotomy, laparoscopy, endoscopy, computed tomographic angiography, angiographic intervention, serial imaging, and clinical observation.

FAST and eFAST are widely available in most of the trauma centers and performed quickly in real time; FAST can be helpful in identifying free fluid suggestive of hemoperitoneum, hemothorax, and hemopericardium while eFAST can help identify pneumothorax, hemothorax, and atelectasis. FAST has acceptable sensitivity (69–98%) for detection of free fluid and lower sensitivity (63%) for detection of solid-organ injury; FAST may lead to underestimation of injuries and severity, especially in the presence of stable trauma patients without detectable free fluid. For detection of free fluid and/or solid-organ injury, FAST has high specificity (94–100%) and serial FAST examinations increase the overall sensitivity (72–93%). The sensitivity of eFAST for pneumothorax and hemothorax is higher than that of chest radiography (11–21% vs. 43–77%). Evaluation of the IVC during FAST can help distinguish between types of shock in hypotensive trauma patients.

CHAPTER

Facial Trauma

Syed Ahmed Adil

INTRODUCTION

Trauma to the facial region causes injuries to skeletal components, dentition as well as soft tissues from the frontal bone superiorly to the mandible inferiorly. Several studies suggest that facial fracture dissipates a lot of force during trauma, in effect protecting the brain. The mandible was the most frequent site involved. Among maxillary fractures, zygomatic bone and arch fractures were most common. The most common causes are motor vehicle crashes, falls, violent assaults, and crashes during bicycling. Cervical spine injury should be considered in a maxillofacial trauma patient until proved otherwise. Up to 44% of patients with severe maxillofacial trauma require endotracheal intubation due to mechanical disruption or massive hemorrhage into the airway.

APPROACH AND MANAGEMENT

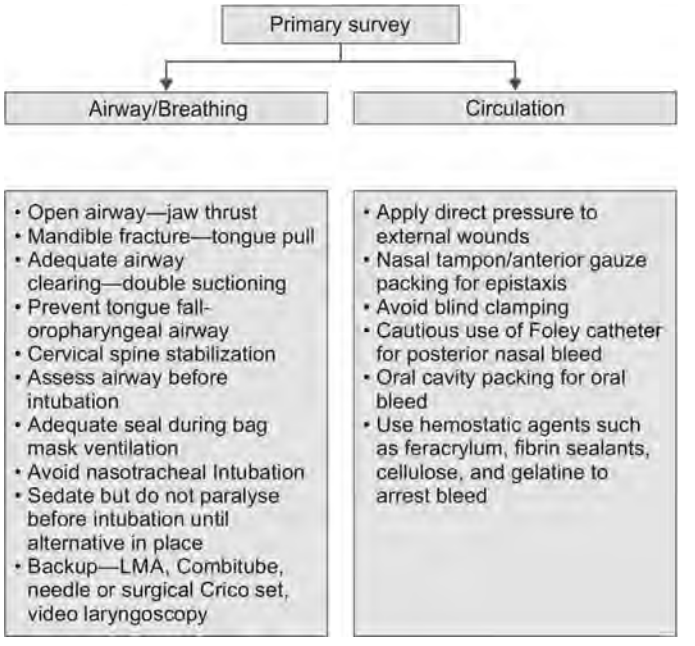
Every trauma patient should be evaluated as per the advanced trauma life support (ATLS) protocol. Primary survey and its management take the utmost priority (**Flowchart 1**). Do not get distracted with other injuries as long as you have airway, breathing, and circulation under control. Next come life-threatening injuries followed by facial injuries. The history indicates the site and direction of force and the possible presence of other injuries, especially to the neck, and other relevant features such as loss of consciousness and head injury. Important issues should be asked/elicited such as vision, facial numbness, bite, pain with eye movements, pain with moving the jaw, and breathing difficulty. Secondary survey includes the following: Inspect the face for asymmetry, inspect open wounds for foreign bodies, and palpate the entire face, supraorbital and infraorbital rims, zygomatic and frontal sutures, zygomatic arch, and oral mucosa.

Sinuses

Frontal bone and sinus injuries usually are a result of a direct blow to the frontal bone with a blunt object. This fracture is frequently associated with intracranial injury, secondary to disruption of the posterior table of the sinus. Dural tears are frequent, and patients may have associated injuries to the orbital roof. Look for disruption or crepitus near the orbital rim. Palpate for subcutaneous emphysema. Look for lacerations or bulging of the forehead. Those with depressed skull fractures and posterior wall involvement should be admitted. A neurosurgical/oromaxillofacial surgery opinion must be obtained. Foreign bodies and bony injuries must be looked for. A patient with frontal sinus injuries may require head, neck, neurological, ENT (ear, nose, throat), and eye examination. Intravenous (IV) antibiotics and tetanus prophylaxis must be considered. Nondisplaced fractures may be treated as outpatients after neurosurgical consultation.

Nose

Nasal fractures account for >50% of all facial fractures in adults (**Table 1**). The bones and cartilage of the nose provide both aesthetic and structural support for the midface and airway;



Primary survey
Airway/Breathing
Circulation
• Open airway—jaw thrust
• Mandible fracture—tongue pull
• Adequate airway clearing—double suctioning
• Prevent tongue fall-oropharyngeal airway
• Cervical spine stabilization
• Assess airway before intubation
• Adequate seal during bag mask ventilation
• Avoid nasotracheal Intubation
• Sedate but do not paralyse before intubation until alternative in place
• Backup—LMA, Combitube, needle or surgical Crico set, video laryngoscopy
• Apply direct pressure to external wounds
• Nasal tampon/anterior gauze packing for epistaxis
• Avoid blind clamping
• Cautious use of Foley catheter for posterior nasal bleed
• Oral cavity packing for oral bleed
• Use hemostatic agents such as feracrylum, fibrin sealants, cellulose, and gelatine to arrest bleed

(LMA: laryngeal mask airway)

FLOWCHART 1: Evaluation of facial injuries.

TABLE 1: Nasal trauma classification.	
Type 1	Injury restricted to soft tissue
Type 2	• 2a: Simple, unilateral, nondisplaced fracture • 2b: Simple, bilateral nondisplaced fracture
Type 3	Simple displaced fracture
Type 4	Closed comminuted fracture
Type 5	Open comminuted fracture

Note: Type II to IV fractures are associated with cerebrospinal fluid (CSF) rhinorrhea, airway obstruction, septal hematoma, crush injury, numbness, severe displacement, or midface involvement.

FIG. 1: Bimanual digital palpation of the nose.

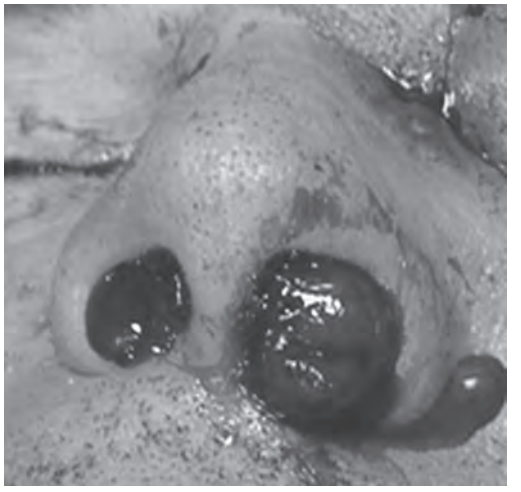


FIG. 2: Septal hematoma. ***(For color version, see plate 38)***

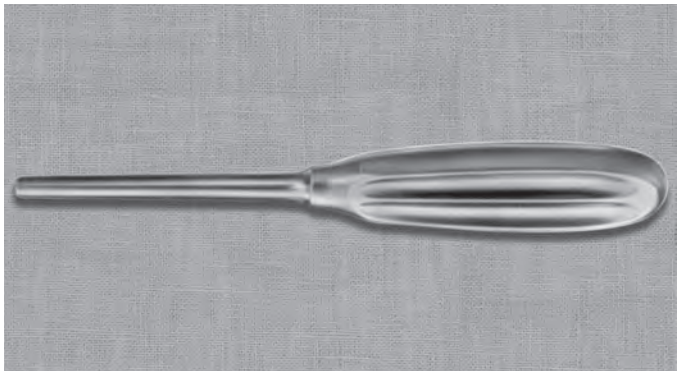

FIG. 3: Goldman's septal elevator.

therefore, proper evaluation and management are necessary to prevent nasal deformity and nasal airway compromise.

Look for asymmetry, tenderness, crepitus, and mobility of the nasal complex. If present, suspect trauma to the nose or medial orbit. Perform bimanual nasal palpation test and check for tenderness over the medial canthus (**Fig. 1**). Inspect the nasal septum for septal hematoma, cerebrospinal fluid (CSF) rhinorrhea, or epistaxis as they may be present. Flattened nasal bridge, widening of the nasal bridge (telecanthus), or a saddle-shaped deformity of the nose suggests nasal bridge fracture with orbital involvement. A septal hematoma appears as a blue/red, boggy, and tender area of swelling along the nasal septum (**Fig. 2**). Control epistaxis by either pinching the nose or anterior/posterior packing. Topical vasoconstrictors can be used. Make the patient sit straight so that he/she does not swallow the blood. Incision and evacuation of the septal hematoma are required to prevent destruction of the cartilage resulting in saddle-nose deformity. To drain septal hematomas, first anesthetize the area. Using a #11 blade, incise the inferior portion of the hematoma and allow it to drain. Then pack the nose with Vaseline gauze to prevent reaccumulation of blood. In the absence of epistaxis or deformity, ice and analgesics may be given. Refer to ENT in 2–5 days for reduction. Rhinorrhea, if present, must be inspected for CSF leak by testing for β-transferrin, glucose, or halo sign. If suspected, a neurosurgical consultation is warranted. The head must be kept elevated and supine positioning avoided to allow healing. Closed reduction is usually reserved for simple, noncomminuted nasal fractures, although exceptions can be made. The key principle is to apply a force opposite to the vector of trauma to achieve fracture reduction. Attention should be paid to the bony nasal pyramid. The Goldman elevator (**Fig. 3**) is applied with upward/outward force with bimanual manipulation of the external nasal bones. Care should be used with this technique over the cribriform plate if injury is suspected.

Ear

Inspect the external auditory canal for any lacerations, CSF leaks, and hemotympanum (**Fig. 4**). Look for battle sign over the mastoid region/auricular hematoma. Check for mandibular condylar fracture by inserting a finger into the external auditory canal and asking the patient to gently open and close the mouth (**Fig. 5**). A number of published studies have shown that the risk of meningitis is significantly reduced when prophylactic antibiotics are used in post-traumatic CSF leakage. Place the patient at bed rest with the head elevated. The basic concept is to decrease intracranial pressure, which in turn should decrease the rate of leakage. Most traumatic leaks will close spontaneously within 7–10 days. If they do not, a neurosurgeon or ENT surgeon should be consulted to consider surgical closure.

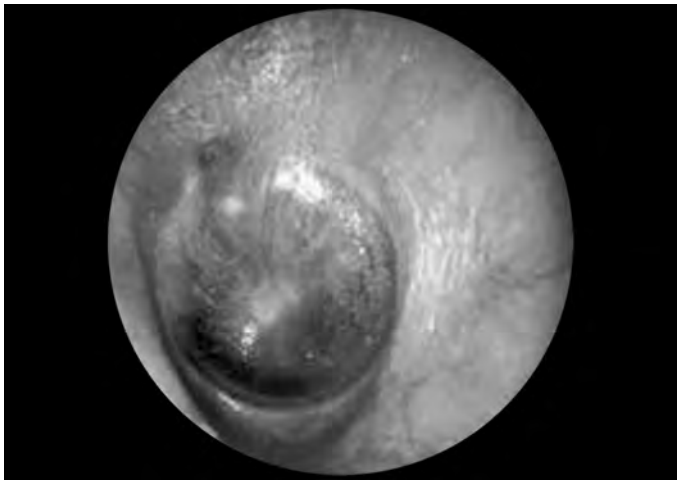

FIG. 4: Hemotympanum. ***(For color version, see plate 38)***

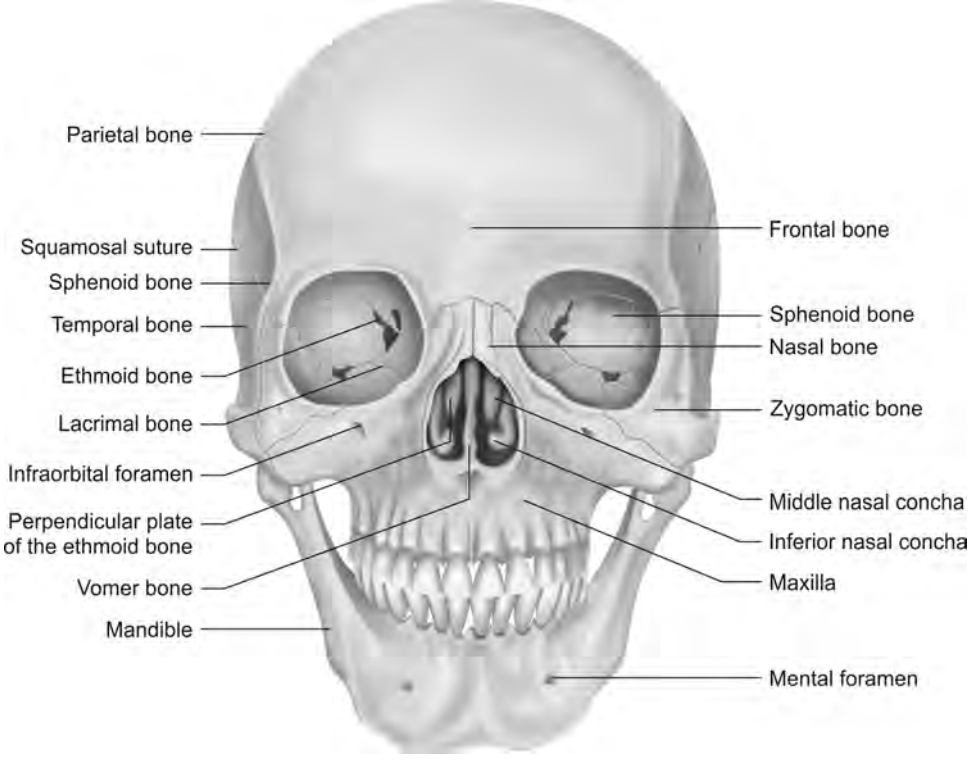

FIG. 6: Facial bones.

MAJOR FACIAL BONES

Major facial bones are shown in **Figure 6**. Zygomatic arch can fracture in two to three places along the arch. These patients present with depressed cheek with tenderness on palpation. The zygomaticomaxillary fracture (tripod fracture) is a rare but complicated fracture (**Fig. 7**). Patients usually present with pain on opening their mouth. Fractures of the maxilla are high-energy injuries. An impact 100 times the force of gravity is required to break the midface. These patients often have significant multisystem trauma. The fractures of the maxilla are classified as Le Fort fractures (**Flowchart 2**). Inspect the face from all sides to detect asymmetry in facial structures from zygomatic, orbital, and Le Fort injuries. Palpate the zygoma along its arch and its articulations with the maxilla and frontal and temporal bones. Open the patient's mouth and grasp the maxilla arch. Place the other hand on the forehead. Push back and forth and up and down and check for movement (**Figs. 8A** and **B**). Emergency care for all these fractures involves airway maintenance, with intubation or cricothyrotomy, if necessary. Airway compromise is probably more common with Le Fort II and III fractures. CSF rhinorrhea is uncommon in Le Fort I fracture but is often seen in Le Fort II and III fractures. If CSF rhinorrhea is present or intracranial air is seen on X-ray or an open skull fracture is present, the patient should be admitted and placed in a head-elevated position (40–60°) if possible. Prophylactic antibiotics are often given to these patients. Patients with maxillary fractures also have significant epistaxis requiring nasal packing. Operative intervention may be needed if bleeding does not resolve

with packing alone. Look for associated injuries, especially intracranial, spinal, thoracic, and abdominal. The incidence of blindness is high for Le Fort II and III fractures, so it is important to get ophthalmology consultation. Patients with complex maxillary fractures require admission for open reduction and internal fixation.

Mandible

Mandibular fractures are the third most common type of facial fracture. Because of their ring shape, fractures are often multiple in up to 50% of the cases. The most common area fractured is the condyle (36%), body (21%), and parasymphysial region (17%). A dental line step-off or ecchymosis of the floor of the mouth is a common finding. There is inability to open the mouth. Periauricular pain while biting is common with condylar fracture. Bilateral body fractures of the mandible may cause airway compromise. Inspect for malocclusion of teeth and bleeding. Ensure that there is no aspiration. Loose and mobile teeth must be counted. Use the tongue blade test to identify fracture of the mandible (**Fig. 9**). Nondisplaced fractures should be treated with adequate analgesia. Orosurgical consultation must be sought. Displaced fractures, open fractures, and fractures associated with dental trauma need urgent orosurgical consultation. These patients require admission and need either closed reduction or open reduction with internal fixation. All patients with mandibular fractures must be administered antibiotics and tetanus prophylaxis.

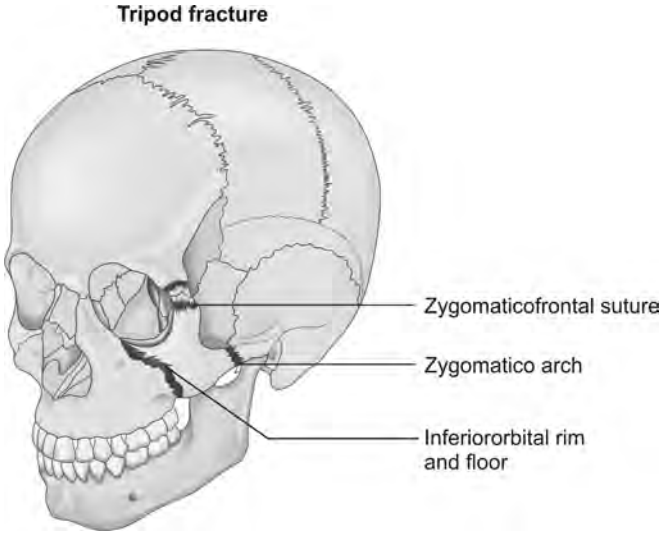

FIG. 7: Tripod fracture.

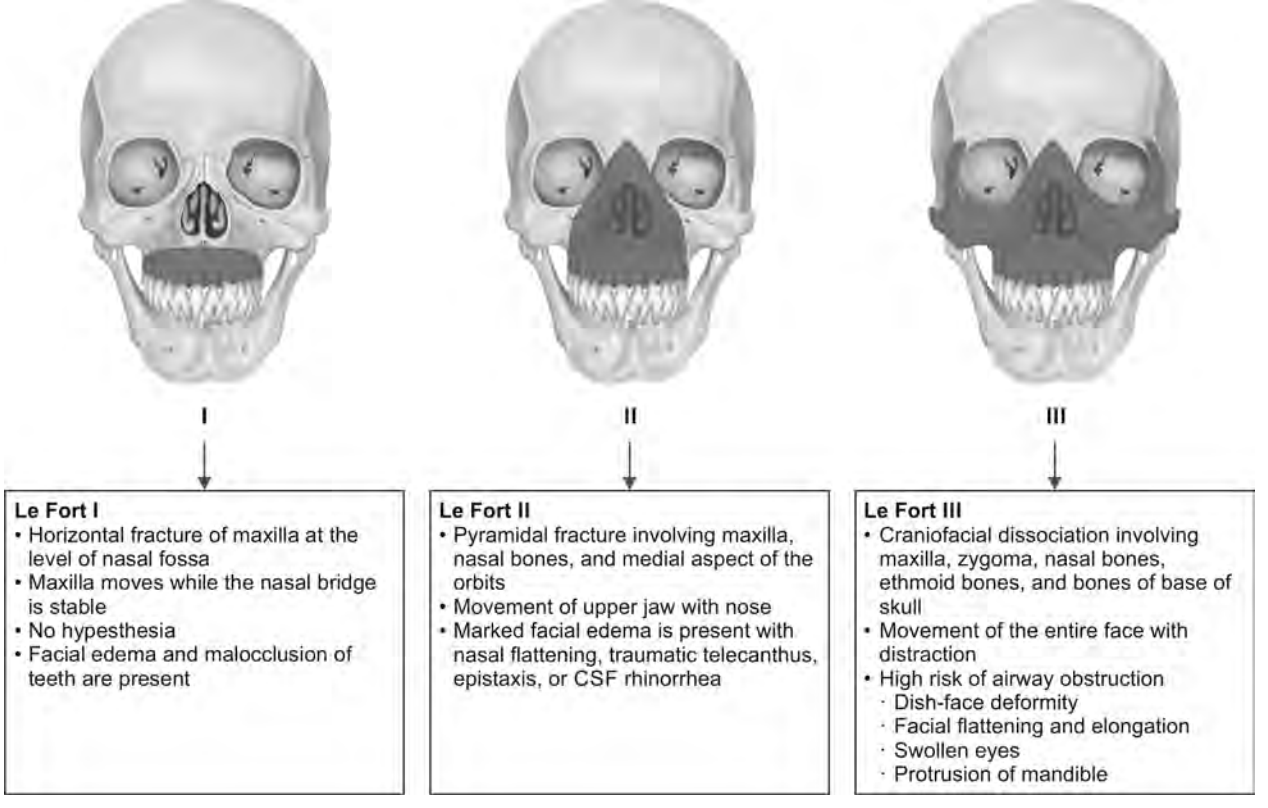
TEMPOROMANDIBULAR JOINT DISLOCATION

Temporomandibular joint (TMJ) dislocation generally results from a direct blow to the chin while the mouth is open or more commonly during vigorous yawning. The mandible can be dislocated in the anterior, posterior, lateral, and superior planes. Anterior dislocation is the most common and occurs when the condyle is forced in front of the articular eminence. Once the jaw is dislocated, muscular spasm of the temporalis and lateral pterygoid muscles tends to prevent reduction. Dislocations are most frequently bilateral, but they also can



I
II
III
Le Fort I
• Horizontal fracture of maxilla at the level of nasal fossa
• Maxilla moves while the nasal bridge is stable
• No hypesthesia
• Facial edema and malocclusion of teeth are present
Le Fort II
• Pyramidal fracture involving maxilla, nasal bones, and medial aspect of the orbits
• Movement of upper jaw with nose
• Marked facial edema is present with nasal flattening, traumatic telecanthus, epistaxis, or CSF rhinorrhea
Le Fort III
• Craniofacial dissociation involving maxilla, zygoma, nasal bones, ethmoid bones, and bones of base of skull
• Movement of the entire face with distraction
• High risk of airway obstruction
· Dish-face deformity
· Facial flattening and elongation
· Swollen eyes
· Protrusion of mandible

FLOWCHART 2: Types of Le Fort fracture.

be unilateral. Unilateral dislocations result in deviation of the mandible to the unaffected side. Bilateral dislocations cause the mandible to be displaced anteriorly (**Fig. 10A**). Posterior dislocations are rare. Lateral dislocations are associated with a jaw fracture. Superior dislocations are associated with cerebral contusions, facial nerve palsy, and deafness. These patients present with the inability to close an open mouth and/or pain, discomfort, and facial swelling. Look for deviation of the mandible or anterior dislocation of the jaw with tenderness and swelling at the angle of the jaw. Paresthesia or anesthesia of the face signifies nerve injury.

Traditional Method of Reduction

Temporomandibular joint dislocation should be reduced with a short-acting muscle relaxant and adequate analgesia. A regional block using 2-mL 2% lidocaine may be given in the preauricular depression anterior to tragus. The patient should be seated. Facing the patient, the examiner places his or her thumbs in the patient mouth, over the mandibular molars as far back as possible. The fingers should curve beneath the angle and the body of the mandible. The examiner applies downward and backward pressure with his or her thumbs until the condyle slides back into the articular eminence. A successful reduction must enable the patient to open his or her mouth immediately (**Fig. 10B**).

Newer External Method

To reduce the *left side*, the thumb is placed just above the anteriorly displaced coronoid process (black arrow) and the fingers are placed behind the mastoid process (gray arrow) (**Fig. 11A**). Simultaneously, on the *right side*, the fingers hold and rotate anteriorly the mandible angle (black arrow) and the thumb is placed over the malar eminence as a fulcrum (gray arrow) (**Fig. 11B**).

EYES/ORBIT

The orbital rim (frontal, maxillary, and zygomatic bones) protects the globe from direct trauma. The weakest parts of the orbit are the medial wall and orbital floor; these fracture first, and the orbital soft tissues can pass through the hole created, causing the globe level to drop (hypoglobus) and sink back (enophthalmos). This is called a pure orbital blow-out fracture. Subconjunctival hemorrhage and chemosis occur with orbital fractures.

Visual acuity, light perception, and pupils must be examined. Look for raccoon eyes (bilateral orbital ecchymosis). Examine the lids for lacerations. Injuries to the medial third of the eyelids can damage the lacrimal apparatus. Test extraocular muscles. Restriction of upward gaze can be seen with zygomatic or infraorbital wall fractures. Examine the cornea for abrasions and lacerations. Examine the anterior chamber for hyphemia. Fundoscopy must be performed for posterior chamber and retinal examination. Palpate the entire orbital rim for tenderness or deformity (**Fig. 12**). Look for hypesthesia of the infraorbital nerve and for periorbital tenderness, swelling, subcutaneous air, ecchymosis, enophthalmos, and impaired ocular motility. Look for infraorbital anesthesia. Check facial stability. Palpate the medial orbit area to rule out naso-ethmoidal-orbital (NEO) fracture. (Place a cotton bud inside the nose to the medial canthus and place your finger outside the medial canthus. If the bone moves, it is known as NEO fractures.)

FIG. 12: Periorbital edema. ***(For color version, see plate 38)***

FIG. 13: Laceration of the eyelid. ***(For color version, see plate 38)***

LACERATIONS

Entrapment injury, pinna laceration or avulsion, and intraoral lacerations must be ruled out. Although suturing is preferred for repair, tissue adhesives are similar in patient satisfaction, infection rates, and scarring risk in low skin-tension areas. Surgical consultation for laceration may be warranted in the following:

- Full-thickness laceration of the eyelid (**Fig. 13**), vermillion cutaneous border of the lip or helical rim of the ear, and free margin of alar rim
- Lacerations involving nerves, arteries, bones, or joints
- Penetrating wounds of unknown depth
- Severely contaminated wounds requiring drainage
- Wounds leading to a strong concern about cosmetic outcome

Reconstruction of laceration or avulsion tongue injuries is not usually required. Primary wound healing often occurs rapidly because of the rich vascular supply. Lacerations larger than 2 cm may require intervention (**Fig. 14**). Deep lacerations should be sutured in layers.

FIG. 14: Laceration of the tongue. ***(For color version, see plate 38)***

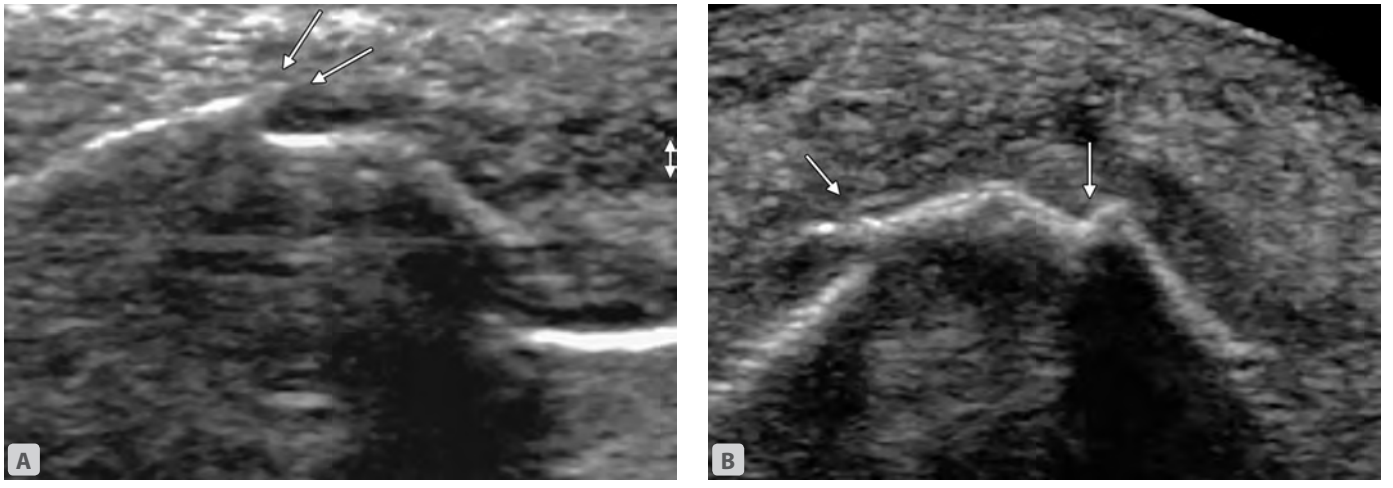
IMAGING STUDIES

Head CT with bone window is a good tool in patients with significant findings of frontal fractures, sinuses, and midface fractures. Plain radiographs remain helpful when CT is not available or to exclude injury in the low-risk patient. The Waters' view X-ray safely replaces the multiple views in a traditional facial series for midfacial fractures. The lateral view for the nose could be helpful. Low-suspicion mandible fractures can be found with the panorex view, but in case of significant findings a mandible CT or a facial CT is warranted. Facial CT with coronal and axial sections is the imaging study of choice for patients with an abnormal Waters' view or as the initial study with significant clinical findings. The other diagnostic tool which is very reliable to detect fracture is ultrasonography (USG). It has been widely used in detecting superficial facial fractures, for example, nasal bone fracture (**Figs. 15A** and **B**), orbital fracture and zygoma fractures in children. It is also used in finding a pupillary reaction through the periorbital edema. Ocular ultrasound plays an important role in differentiating orbital ultrasound from the normal orbit (**Fig. 16A**). It can also detect ocular injuries such as retrobulbar hemorrhage, which is also known as guitar-pick sign (**Fig. 16B**), retinal detachment (**Fig. 16C**), and lens dislocation (**Fig. 16D**).

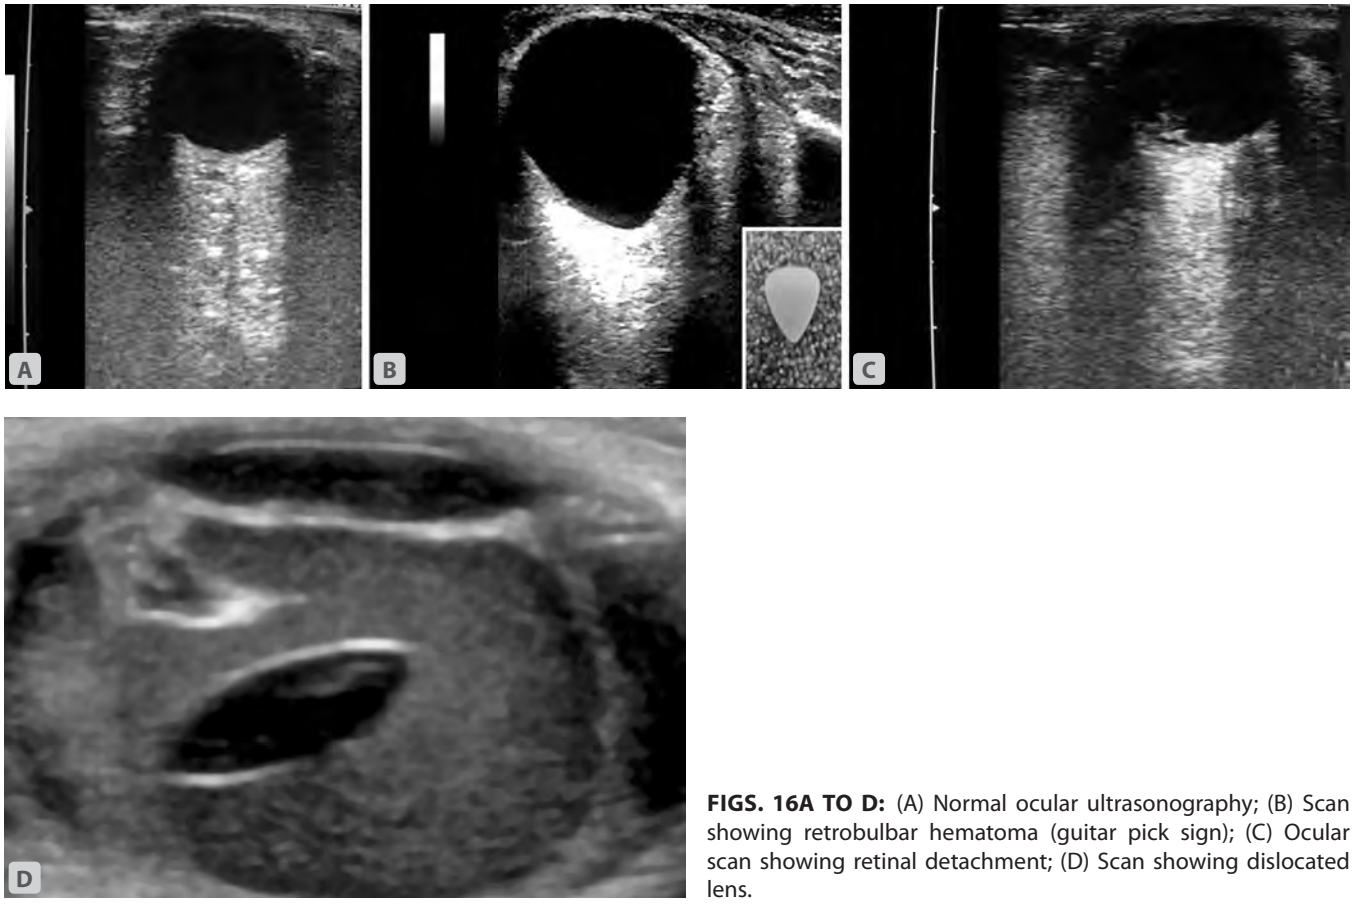
Classic tests for CSF rhinorrhea are not accurate in distinguishing CSF from serous nasal discharge in the presence of nasal bleeding. The double-ring or halo sign occurs when clear CSF diffuses around blood when dropped on a paper towel. The glucose test is likewise not reliable. Nasal discharge does not contain glucose, whereas CSF does. Blood from the injury may create a false-positive test. A beta 2 transferrin assay marker is very specific to CSF. However, the test is expensive and results may take several days to a few weeks. In the absence of a CT scan, X-ray along with USG can detect most of the injuries.

SUMMARY

Facial trauma is a common complaint in the emergency department. Interventions can range from simply diagnosing a fracture and providing referral to very complex management of severe fractures requiring stabilization of the airway,

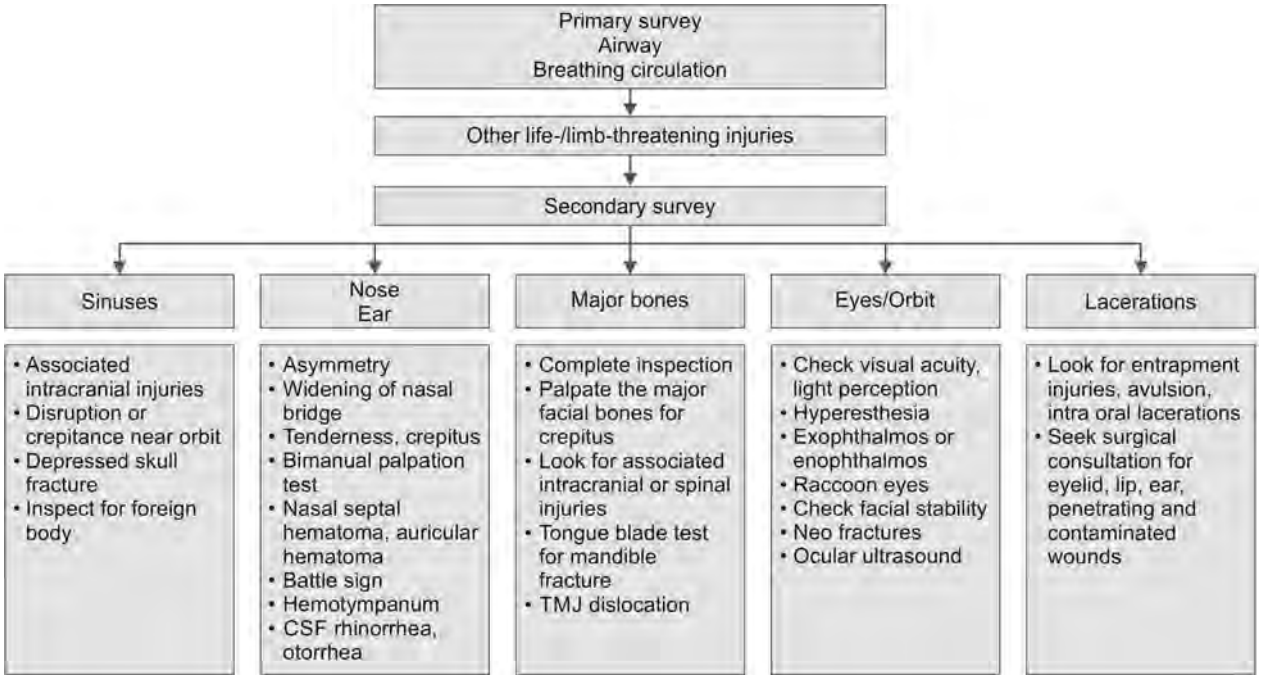


FIGS. 15A AND B: (A) Longitudinal scan of left nasal bone shows depressed fracture. (B) Marked soft-tissue edema and hyperechoic hematoma near depressed fracture lines.



FIGS. 16A TO D: (A) Normal ocular ultrasonography; (B) Scan showing retrobulbar hematoma (guitar pick sign); (C) Ocular scan showing retinal detachment; (D) Scan showing dislocated lens.

hemostasis of active bleeding, and proper evaluation and management of many aspects of trauma. It is vital that emergency physicians recognize associated injuries, including those affecting the brain and cervical spine, as common associations in facial trauma. The emergency physician must always maintain a high degree of suspicion and should evaluate all complaints of facial trauma thoroughly (**Flowchart 3**), because a missed injury can threaten life or vision. A methodical and organized examination is paramount for patient safety and the physician's documentation of the evaluation. CT scans are the most efficient and comprehensive way to evaluate facial trauma and fractures and should be used liberally in patients with any concern for soft tissue or bony injury and especially in those who are unable to provide a reliable examination. CT scans of the head and cervical spine can be life-saving. Many injuries are obscured by swelling or ecchymosis. It is always safer to consult a facial surgeon in the setting of uncertainty. In patients who are safe for discharge, it is the responsibility of the emergency physician to provide clear instructions regarding close follow-up.



(CSF: cerebrospinal fluid; TMJ: temporomandibular)

223
CHAPTER

Head Trauma

Prasad Rajhans, Harshwardhan Singh Pawar, Devendra Richhariya

INTRODUCTION

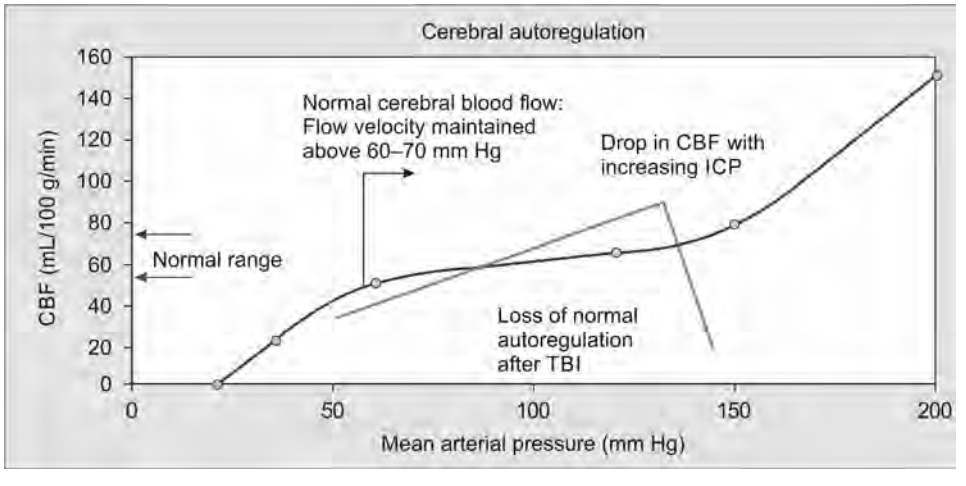
Trauma to the central nervous system (CNS) (the brain and spinal cord) can be classified on the basis of mechanisms of injury, clinical severity, radiological appearance, or anatomic distribution. Education regarding preventive measures of head trauma is important for public, such as the use of helmets and seatbelts. The main objective in the management of patients with head trauma is the prevention of secondary injury such as ischemia and hypoxia. This chapter includes common neurologic injuries related to trauma and their prehospital, in-hospital, and critical care management in patients.

Head trauma is a critical situation and the leading cause of death worldwide. It can be classified based on:

- Mechanism of injury—contact/impact loading and noncontact/inert loading
- Severity of injury—mild, moderate, severe
- Pathoanatomic—based on the location and anatomic feature of injury
- Pathophysiologic—primary injury and/or secondary injury

CEREBRAL BLOOD FLOW AND AUTOREGULATION

The CNS is enclosed in a bony vault. It comprises brain parenchyma, cerebrospinal fluid (CSF), and blood. In normal physiology, these three elements are in homeostasis. An adult brain represents 2% of body weight. It receives 12–15% of total cardiac output. This represents the high metabolic rate of brain parenchyma. Cerebral blood flow (CBF) is 45–55 mL/100 g/min, cerebral metabolic rate of oxygen is 3–3.5 mL/100 g/min/mL, and intracranial pressure (ICP) (supine) is 8–12 mm Hg. Normal CBF is maintained by cerebral blood vessels by its constriction and dilatation ability under various physiological conditions. This is called autoregulation. Factors affecting CBF are temperature, seizures, partial pressure of carbon dioxide ($PaCO_2$), partial pressure of oxygen (PaO_2), mean arterial pressure (MAP), and vasoactive agents. Normal functioning of the brain is dependent upon the cerebral perfusion pressure (CPP) which is the difference between the MAP and the ICP: *CPP = MAP – ICP*. CPP roughly denotes CBF. CBF is maintained well when MAP is maintained between 60 and 150 mm (**Fig. 1**).



(CBF: cerebral blood flow; ICP: intracranial pressure; TBI: traumatic brain injury)

FIG. 1: Determinants of cerebral blood flow.

PATHOPHYSIOLOGY OF TRAUMATIC BRAIN INJURY

Knowledge of the Monro–Kellie doctrine is essential to understand brain pathophysiology in injury. In 1783, Alexander Monro deduced that the cranium is a rigid box and is filled with the nearly incompressible brain and that its volume remains constant. In 1824, George Kellie confirmed Monro's observation. The doctrine states that any increase in the volume of the cranial contents raises the ICP and the increase in the volume of the content occurs at the expense of the other two. The initial reaction is to reduce venous blood and CSF. When these compensatory mechanisms get exhausted, the pressure increases drastically, and brain herniation can occur (**Fig. 2**).

Head trauma leads to brain parenchymal injury which is termed traumatic brain injury (TBI). TBI is defined as any disruption in the function of brain due to external force. TBI is due to falls, road traffic accidents, blunt head injury, assault, blast injury, and sometimes child abuse. The ability of autoregulation and maintenance of CBF get disrupted when any TBI occurs. Cerebral vasoconstriction occurs due to hypertension, alkalosis, and hypocarbia and cerebral vasodilation occurs due to hypotension, acidosis, and hypercarbia. After TBI increase in intracranial blood volume (due to vasodilatation) causes brain swelling, it is the compensatory mechanism of the brain to maintain optimal CBF in view of damaging brain tissue. Secondary to TBI, various devastating intracranial and extracranial events occur such as severe intracranial hypertension, seizures and cerebral edema, hypotension, hypoxia, anemia, and hyper- and hypocapnia. These devastating events determine the final outcome in the patient after TBI. Hypotension and hypoxia clearly worsen the patient outcome. In short, pathophysiology of TBI involves alteration in CBF, parenchymal injury, cerebral edema, ICP, and herniation (**Fig. 3**).

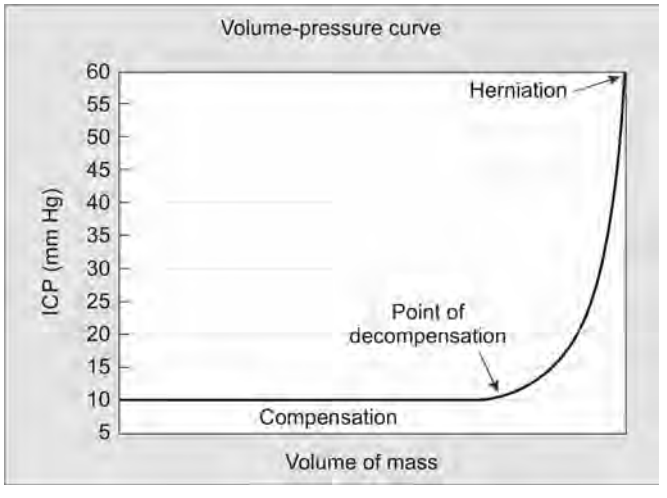


FIG. 2: Intracranial pressure (ICP) versus volume curve.

MECHANISM OF INJURY

Blunt Injuries

Blunt injuries mean acceleration and deceleration of brain after a direct blunt impact to the head.

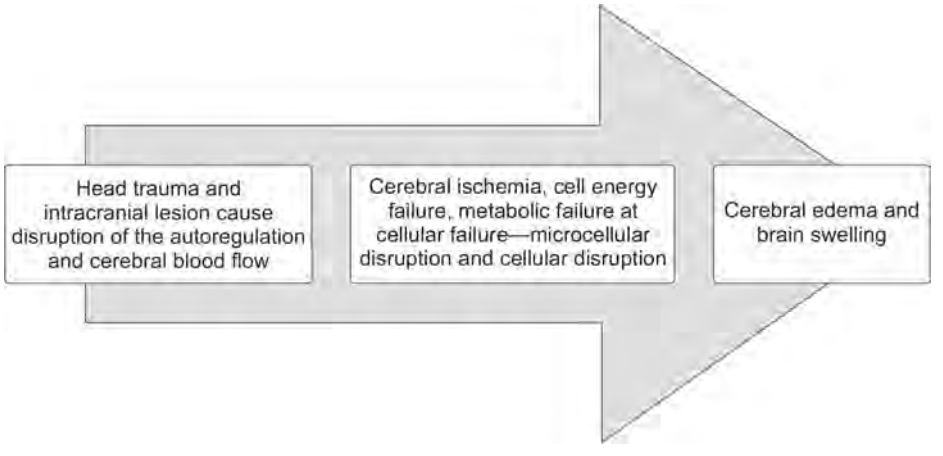
Blunt impact-induced mechanical forces cause tissue compression, distortion, and shearing, resulting in parenchymal contusions, extra-axial hematomas, and diffuse axonal injury (**Table 1**).

Penetrating Injuries

Penetrating brain injuries are less common than blunt injuries and having high mortality rates. The most frequent penetrating brain injury in the emergency department is a gunshot injury/firearm injury. High-velocity projectile penetrates the brain and damages the parenchyma.

CONSEQUENCES OF TRAUMATIC BRAIN INJURY

Any trauma to brain leads to two different but inter-related consequences: (1) *Primary injury;* and (2) *Secondary injury.* Primary injury to the brain is caused by external mechanical force transferred to the bone, brain parenchyma, blood vessels, and CSF. The mechanism involved is acceleration–deceleration, shear force, direct impact. Consequently, it leads to (1) skull fracture—linear, stellate, nondepressed, depressed; (2) brain parenchymal injury—contusion, diffuse axonal injury; and (3) blood vessel injury—epidural hematoma (EDH), subdural hematoma (SDH), and subarachnoid hemorrhage (SAH). Secondary injury to brain results because of alteration in brain homeostasis. It involves a series of molecular mechanisms as a consequence of inflammation, disruption of the blood–brain barrier, free radicle injury, and cell swelling.



Head trauma and intracranial lesion cause disruption of the autoregulation and cerebral blood flow
Cerebral ischemia, cell energy failure, metabolic failure at cellular failure—microcellular disruption and cellular disruption
Cerebral edema and brain swelling

FIG. 3: Pathophysiologic changes in traumatic brain injury.

TABLE 1: Blunt trauma and pattern of brain injuries.

	Pathophysiology	*Anatomical location*	*Special features*
Parenchymal contusion	Coup/countercoup injury	Frontal or temporal	Can expand within 24 hours
Epidural hematoma	Disruption of middle meningeal vessels, diploic vein, and venous sinuses	Near skull fracture	Lens shaped (convex)
Subdural hematoma	Bridging vein injury	Cerebrum tentorium and falx	Crescent-shaped (concave)
Subarachnoid hemorrhage	Pial vessels injury	Cerebrum basal cistern ventricles	Can be limited to few sulci fissure or diffuse
Diffuse axonal injury	Shear injury of axonal	At cortex and white matter junction	Axonal swelling and axotomy

Cell membrane disruption leads to flux of sodium and calcium that causes activation and release of excitatory neurotransmitters such as glutamate and excessive stimulation of cell. This mechanism is called excitotoxicity. Activation of enzyme due to calcium influx leads to free oxygen radical generation and injury. Also, activation of proteases leads to disruption of cytoskeleton and caspases lead to cell cycle disruption. Cell death occurs via necrosis and pathological apoptosis. There is disruption of cell membrane and blood–brain barrier leading to cytotoxic and vasogenic edema, respectively. Brain edema can lead to raise ICP, which in turn can cause compression-induced ischemia. Secondary injury is accentuated by hypoxemia, hypercapnia/hypocapnia, hypotension/hypertension, hyperthermia, hyperglycemia, and dyselectrolytemia.

Brain herniation is of four types: (1) Uncal transtentorial, (2) central transtentorial, (3) cerebello-tonsillar, and (4) upward posterior fossa.

Uncal transtentorial herniation is the most common. It is seen with a lesion in the temporal lobe or middle fossa. The uncus part of the temporal lobe herniates through the tentorium. It compresses the outer parasympathetic fiber of the oculomotor nerve, which causes fixed mid-dilated pupils on the ipsilateral side and pyramidal tract which causes contralateral hemiparesis. Central transtentorial herniation occurs with the midline lesion present in the frontal occipital or vertex. It causes bilateral pinpoint pupils, bilateral Babinski reflex, and increased muscle tone. Cerebello-tonsillar herniation occurs when the cerebellar tonsil herniates through the foramen magnum. It causes bilateral pinpoint pupil, flaccid paralysis, and sudden death. Upward transtentorial herniation results from a posterior fossa lesion and leads to a conjugate downward gaze with absence of vertical eye movements and pinpoint pupils.

PATTERN OF BRAIN INJURIES

Skull Fracture

Skull fractures occur because of external force. They are of the following types: linear, stellate, depressed, nondepressed, open, closed, basilar, and vault. A CT scan with bone window is required to make a diagnosis of skull bone fractures. Skull fractures are often associated with intracranial injury. Basilar skull fractures cause retro-orbital ecchymosis racoon eyes, retroauricular ecchymosis (Battle's sign), CSF leak from the nose and ear, and injury to VII and VIII cranial nerves. These signs should raise a suspicion of basilar fracture. Sometimes, a fracture can travel to the carotid canal and cause injury to the carotid arteries. A temporal bone fracture can injure the middle meningeal artery (MMA) and cause EDH. Open fractures and CSF leaks can cause infection in the CNS as they provide the portal of entry to microbes.

Intracranial Injuries

These can be classified as diffuse and focal, e.g., diffuse brain injuries and concussion.

Diffuse axonal injury is caused due to shearing force and diffuse injury is caused due to hypoxemia. *Concussion* is a nonfocal transient disturbance in the brain. *Diffuse axonal injury* occurs at the interface of gray and white matter. It results from shearing force on axons. It is usually seen in high-velocity injury and acceleration–deceleration injury. It causes punctate hemorrhage in the brain parenchyma.

Intracranial hemorrhage: It occurs in 46% of cases with TBI. It is associated with an increase in morbidity and mortality. It includes the following:

Epidural hematoma: It occurs in 22.5% of TBI. EDH develops after direct mechanical force over the skull and skull fracture. The most common site for EDH is the temporoparietal region, mostly unilateral and in young individuals. The classic presentation of lucid interval is seen in about 30% of patients. It is an extra-axial intracranial hematoma between the inner table of the skull bone and the dura mater. It causes the lenticular (biconvex) shape hematoma on a noncontract computed tomography (CT) scan (**Fig. 4**). The meningeal arteries lie between the dura mater and the skull in epidural space. The hematoma occurs due to injury to MMA which is in temporal fossa and associated skull fracture. It does not cause the suture line as dura mater is attached at the suture line of the skull. As it is an arterial bleed, it causes rapid intracranial bleed and significant mass effect and midline shift. The classic clinical attribute is the lucid interval which is typically present as an initial loss of consciousness following trauma,then complete transient recovery (lucid interval) followed by rapid progression of neurological deterioration. It is a neuroemergency and may require hematoma evacuation. Antiedema agents should be avoided as they can readily expand the hematoma by intracranial dehydration. The mortality in EDH is approximately 23%.

Subdural hematoma: SDH, developed between the dura mater and brain, is mostly due to a fall from height and acceleration–deceleration injury is due to a road traffic accident. SDH is more common than EDH. It is the most common intracranial injury associated with TBI. The dura mater splits into two leaves and encloses the venous sinuses. The intracranial hematoma

occurs due to disruption of bridging veins that drains blood to venous sinuses from brain parenchyma. This is common in the elderly. The clinical features of an SDH depend upon the patient's age, the presence of polytrauma, or the presence of altered mental status from a nontraumatic cause (e.g., alcohol or drug intoxication).

It appears as concave (crescent) shaped and crosses the suture line on the CT scan of the brain (**Fig. 5**). It is limited by falx cerebri. It is often associated with parenchymal injury. It is associated with 33% mortality in TBI.

Subarachnoid hemorrhage: It occurs in 22% of TBI. The bleeding occurs in the subarachnoid space which lies between the arachnoid mater and the pia mater and filled with CSF. Pia mater is firmly attached to brain parenchyma. SAH results from an injury to corticomeningeal vessels. It is often associated with brain contusion. It generally does not produce mass effect and mile shift and can cause a rise in ICP due to obstructive hydrocephalus (HCP). It can also cause an ischemic injury to cells through vasospasm of the vessel due to extravasation of hemoglobin. It is associated with the highest mortality of 40%.

Intraparenchymal bleed: It occurs in 21% of patients with TBI. The hemorrhage occurs in brain parenchyma. It is associated with brain edema and mass effect. Significant intracranial bleed can cause compression and herniation of brain parenchyma. It can cause compression ischemia in opposite-side brain parenchyma due to raised ICP. It is associated with 31.8% mortality.

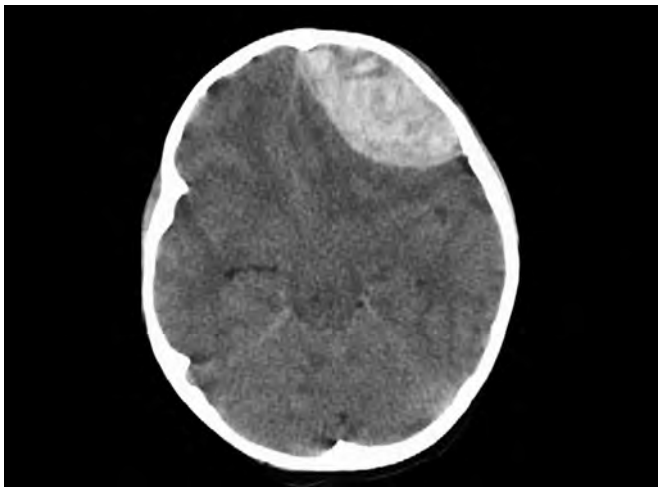


FIG. 4: Noncontrast CT scan image of epidural hematoma.

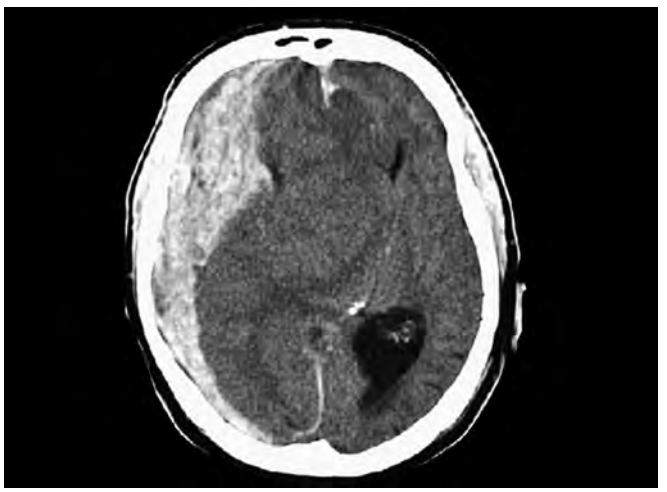

FIG. 5: Noncontrast CT scan image of subdural hematoma.

Contusion: It is a focal heterogeneous lesion that consists of punctate hemorrhage, edema, and necrosis. It is commonly associated with the acceleration–deceleration mechanism of injury. It is mostly seen in inferior frontal and anterior temporal lobes. The contusion can occur at the site of impact, coup and opposite to it, countercoup. So, the part of skull and brain that lies diagonally opposite to the impact should be checked.

TRAUMATIC BRAIN INJURY—ACCORDING TO SEVERITY

Traumatic brain injury can be classified on the basis of Glasgow coma scale (GCS) as mild GCS 14–15, moderate GCS 9–13, and severe GCS < 8.

Mild Traumatic Brain Injury

Concussion

Concussion is a transient, brief disruption of the neurologic function after a minor blunt trauma to the head, with or without a loss of consciousness, usually as a result of acceleration–deceleration forces to the head. Usually, the patient presents with symptoms of headache, confusion, and amnesia. Headaches, sensory sensitivity, memory or concentration difficulties, irritability, sleep disturbances, or depression may persist for a long period after a concussion, termed postconcussion syndrome.

Moderate and Severe Traumatic Brain Injury

A moderate TBI patient has a GCS score of 9–13. Pateint can present with a variety of clinical features such as worsening headache and nausea, confusion, seizure, and loss of consciousness. The patient may present with isolated facial trauma or polytrauma associated with focal neurologic deficits. The emergency physician should be more cautious while managing this type of patient. Initially, patients are able to talk but gradually their GCS score deteriorates significantly and are consistent with severe TBI (talk and deteriorate patient). Most of the patients have extra-axial hematomas, epidural or subdural. These patients have better clinical outcomes if detected early and treated rapidly. Successful management depends upon frequent assessment of GCS score, close observation for minor mental status changes or focal neurologic findings, frequent use of CT scanning, and early neurosurgical intervention.

In the emergency department, if the patient presents with moderate TBI with herniation, immediate interventions such as hyperventilation and osmotic therapy should be initiated and consideration should be given for surgical evacuation of hematoma before transferring to a definitive care unit. All moderate TBI patients should undergo a CT scan and should be admitted to the observation unit for frequent neurological examination and monitoring; a repeat CT scan should be done if required.

Severe TBI is when the patient presents acutely with a GCS score of 8 or less. Any intracranial contusion, hematoma, or brain laceration is considered as severe TBI. A patient with severe TBI and with an increase in ICP presents with symptoms of progressive hypertension, bradycardia, and shallow or

irregular respiration (Cushing's reflex/phenomenon). These features represent the life-threatening raised ICP and require urgent ICP management such as hyperventilation osmotic therapy and surgical decompression.

CLINICAL FEATURES OF TRAUMATIC BRAIN INJURY

Symptoms vary and depending on the severity of the head injury, these may include any of the following: Vomiting, lethargy, headache, confusion, paralysis, coma, loss of consciousness, dilated pupils, vision changes (blurred vision or seeing double, not able to tolerate bright light, loss of eye movement, blindness), CSF (which may be clear or blood-tinged) coming out of the ears or nose, dizziness and balance problems, breathing problems, slow pulse, slow breathing rate, with an increase in blood pressure, ringing in the ears or changes in hearing, cognitive difficulties, inappropriate emotional responses, speech difficulties (slurred speech, inability to understand and/or articulate words); difficulty swallowing, body numbness or tingling, droopy eyelid or facial weakness, and loss of bowel control or bladder control. Signs of herniation include irregular pupil, abnormal flexion or extension, and Cushing triad—hypertension, bradycardia, and irregular breathing.

GUIDELINES FOR MANAGEMENT OF HEAD INJURIES

Guidelines are for effective clinical assessment and management of a patient with head injury. They promote the best and appropriate treatment to the person with head injury and are also for their families and their attendants so that they have the knowledge about what should be done for the betterment of the injured person. Also, include referral guidelines in cases where specialist care is needed.

Prehospital Care

Initial assessment: It should start with the "Glasgow coma scale" and the score should be recorded or communicated properly on every note. *Children with head injury should be assessed and managed according to* advanced pediatric life support. *Adults with head injury should be assessed and managed according to* advanced trauma life support (ATLS) course.

Immediate care at the scene: Cervical collar should be applied in case of suspected head injury:

- GCS < 15 on initial assessment
- Neck pain or tenderness
- Focal neurological deficit
- Paresthesia in the extremities
- Any other clinical suspicion of cervical spine injury

It manages pain effectively, gives assurance to the patient and family, and supports limb fractures and Foley's catheterization.

Emergency Department Care

Assessment of all head injuries of the patients should be done within 15 minutes of arrival:

- Airway, breathing, and circulation (ABC) assessment and management
- Assessment of risk factors
- CT of head and cervical spine imaging and other body areas
- Conscious patient should be assessed immediately
- An anesthetist or critical care physician should provide appropriate airway management and assist with resuscitation in a patient with GCS 8 or less.
- A standard head injury *pro forma* should be used for documentation.

Investigations for Clinically Important Brain Injuries

Acute clinically important brain injuries should be investigated by CT imaging of the head using minimum radiation dose. Magnetic resonance imaging (MRI) should be performed depending on the need but should not be the primary investigation. There is no role of X-ray of skull. *The criteria for performing a CT head scan* are as follows:

- GCS < 13 on initial assessment in the emergency department
- GCS < 15 at 2 hours after the injury on assessment in the emergency department
- Open or depressed skull fracture
- Features of basal skull fracture
- Post-traumatic seizure
- Focal neurological deficit
- Vomiting
- Elderly group
- Any history of bleeding or clotting disorders
- Retrograde amnesia of events immediately before the head injury

In all the above-mentioned cases, a provisional written radiology report should be made available within 1 hour of the scan being performed. The risk stratification of head trauma in the emergency department is helpful in triaging the high-risk patient and prioritize for the management (**Table 2**).

RESUSCITATION AND MANAGEMENT OF HEAD TRAUMA IN THE EMERGENCY DEPARTMENT

Airway, Breathing, Circulation

Head trauma management started with assessment and stabilization of the airway, breathing, and circulation, like any other critically ill patient. Rapid-sequence endotracheal intubation with in-line stabilization of the cervical spine should be considered for airway protection for patients with a GCS < 8. Maintain PaO_2 > 60 mm Hg and saturation > 90%. Hypoxia and hypotension are associated with increased mortality. Maintain normocarbia ($PaCO_2$ around 35 mm Hg) and avoid hyperventilation in a patient with TBI; hyperventilation produces vasoconstriction and further ischemia which decreases cerebral perfusion. Similarly, hypercarbia produces vasodilation and raised intracranial tension and clinical deterioration. Use of hyperventilation should be restricted only to acutely herniating and deteriorating patients while arranging for emergency craniotomy.

Fluid Resuscitation

Choosing the right fluid is an important aspect for head trauma management. Maintain normovolemia by intravenous fluid, blood, and blood products. Ringer's lactate and normal saline

TABLE 2: Risk assessment in a head trauma patient in the emergency department.

High-risk head trauma	*Medium-risk head trauma*	*Low-risk head trauma*
• Focal neurologic deficit • Unequal pupils • Skull fracture • Polytrauma • GCS score of <8 • Unconsciousness • Post-traumatic confusion • Worsening headache • Vomiting • Post-traumatic seizure • Associated intoxication • Unreliable history of injury • Age older than 60 years or younger than 2 years	• Initial GCS score of 13–15 • Brief period of LOC • Post-traumatic amnesia • Vomiting • Headache • Intoxication	• Asymptomatic • Conscious • Well orientation/memory • Accurate history • No other injuries • Normal neurological exam • Normal pupils • GCS score of 15 • Injury of >24 hours' duration • No/mild headache • No vomiting

(GCS: Glasgow coma scale; LOC: loss of consciousness)

are ideal solutions for resuscitation of TBI. Hypotonic and glucose-containing fluid should not be used. A normal serum sodium level should be maintained. Hyponatremia causes brain edema. A vasopressor can be used in neurogenic shock due to spinal cord injury.

Measures to Maintain Intracranial Pressure

It is important to maintain an equal volume of each compartment (brain, blood, CSF) of skull. If the volume of one component is increased [due to space-occupying lesion (SOL), intracranial hemorrhage, edema], then the volume of other components should decrease as a compensatory mechanism. A mismatch in the compensatory mechanism leads to a rise in ICP; a decrease in CPP ultimately causes cerebral ischemia. ICP monitoring is preferred in severe traumatic injury by placing external ventricular drain which is helpful in measuring the global ICP and controlling it by CSF drainage. Mannitol is helpful in reducing the raised ICP. It should not be used in hypotensive patients. It is highly recommended as bolus (1 g/kg) in an acutely deteriorating and herniating patient provided the patient is normovolemic normotensive.

Hypertonic saline is also helpful in reducing the raised ICP. Three percent concentration is frequently used and hypertonic saline can be used in a hypotensive patient. Barbiturates are also helpful in reducing the raised ICP but should not be used in a hypotensive and hypovolemic patient; hence, it is not helpful in an acute resuscitative phase. Hypothermia is also helpful in reducing the raised ICP. Prophylactic hypothermia is neuroprotective and beneficial effects are seen in severe TBI.

Anticonvulsant

The possibility of seizure in head trauma increases with an increase in the severity of head injury. Patients with severe TBI are more prone to seizures. Seizure can be controlled by anticonvulsant such as phenytoin, fosphenytoin, diazepam and lorazepam. Seizures should be controlled as soon as possible to prevent secondary brain injury. In an adult, the loading dose of phenytoin is 1 g and then the maintenance dose is 100 mg every 8 hours.

Antibiotics

There is a high possibility of infection rate in a patient with severe TBI. Prophylactic antibiotics can be used in a patient with basal skull fracture and CSF leak in view of risk of meningitis. The risk of infection also exists in a patient with external ventricular drain.

Scalp Wound

It should be inspected carefully and adequately cleaned. Stop hemorrhage by applying direct pressure or bleeding vessels ligation. Sutures or staples can be applied. CT scan of the head should be performed to exclude or confirm the skull fracture. The advice of a neurosurgeon should be taken for all cases of open/depressed skull fracture.

Penetrating Brain Injuries

A CT scan is appropriate in locating the bullet foreign bodies and intracranial air. Angiography is helpful in identifying the traumatic aneurysm and arteriovenous fistula. In these cases, endovascular management is helpful. Start prophylactic antibiotics and early ICP monitoring.

Do not remove any penetrating objects such as knife arrow before vascular injury assessment or definitive surgical management, otherwise fatal hemorrhage may occur.

Neurosurgical Consult

A neurosurgeon should be consulted in each and every case of head injury and for further follow-up. The most important indications for urgent neurologic consult are coma, confusion, focal neurological deficit, seizure, penetrating injury, And skull base fracture with CSF leak.

Communication with Families and Attendants

The attending and admitting physician should brief the families about the overall condition and explain what they are doing. The team of doctors managing the patient should share information about possible complex changes in the patient with family members.

Transfer of Child or Adult from a Hospital to a Neuroscience Unit

- Patient should be transferred to a neuroscience unit oy after completing the initial resuscitation and stabilization and establishing comprehensive monitoring.
- Use intubation and ventilation before transfer.
- Patient should be accompanied by a trained and experienced doctor and assistant in emergency cases and by clinical staff in a nonemergency condition.

During transfer, family members must be given full access to the patient as is practical.

Admission and Observation

Head injury should be admitted under the care of a trained neurosurgery team

- Patients with clinically significant abnormalities on neuroimaging
- Patients with low GCS regardless of the neuroimaging results
- CT scanning could not be done due to patient irritability
- Persistent vomiting and severe headaches
- Drug or alcohol intoxication, suspected nonaccidental injury, meningism, CSF leak

Observation of Admitted Patients

A patient admitted with head injury should be observed only by trained clinicians for neurological observations such as GCS, pupil size and reactivity, limb movements, respiratory rate, heart rate, blood pressure, temperature, and blood oxygen saturation. These should be performed and recorded on a half-hourly basis until GCS of 15 has been achieved. After that, it should be done half-hourly for 2 hours, then 1-hourly for 4 hours, and then 2-hourly thereafter.

Any deterioration should be informed to the supervising team:

- New development of agitation
- Decrease of even 1 point in GCS score
- Severe or increasing headache or persisting vomiting
- New development such as pupil inequality or asymmetry of limb or facial movement
- In all the above cases, an immediate CT scan should be considered.

Discharge and Follow-up

Patients can be discharged, if there is no indication for a CT scan of the head and no other factors (such as drug or alcohol intoxication, other injuries, shock) are present. Patient can be discharged if CT head and cervical spine is normal and GCS 15 with normal clinical examination. Patients admitted following a head injury may be discharged after resolution of all significant symptoms and signs.

Advice on discharge and follow-up: Provide a printed discharge summary to all patients with any kind of head injury and to their families. A printed summary should focus on:

- Details about head injury and recovery process
- List of dangerous symptoms when they need to contact the emergency department
- Contact details of the hospital services treating team
- Medication chart

Any patient who has residual problems should be managed as outpatient by a team of neurologist, neurosurgeon, clinical psychologist, and rehabilitation medicine specialist.

SUMMARY

Head trauma leads to brain parenchymal injury which is termed traumatic brain injury. TBI is due to falls, road traffic accident, blunt head injury, assault, blast injury, and sometimes child abuse. TBI involves alteration in CBF, parenchymal injury, cerebral edema, ICP, and herniation. Head trauma is a critical situation and leading cause of death worldwide. Education regarding preventive measures of head trauma is important for public, such as the use of helmets and seatbelts. An emergency physician should have in-depth knowledge of common neurologic injuries related to trauma and their prehospital, in-hospital, and critical care management in patients (**Table 3**).

TABLE 3: Management of traumatic brain injury (TBI).

Severity of TBI	*Mild TBI*		*Moderate TBI*	*Severe TBI*
Initial management	AMPLE history and neurological exam: Ask particularly about use of anticoagulants		Neurosurgery evaluation or transfer required	Urgent neurosurgery consultation or transfer required
	May discharge if admission criteria not met	Admit for indications below:	Primary survey and resuscitation	Primary survey and resuscitation
	• Determine mechanism, time of injury, initial GCS, confusion, amnestic interval, seizure, headache severity, etc. • Secondary survey including focused neurological exam	• No CT available • CT abnormal, skull fracture, CSF leak • Focal neurological deficit • GCS does not return to 15 within 2 hours	• Arrange for transfer to definitive neurosurgical evaluation and management • Focused neurological exam • Secondary survey and AMPLE history	• Intubation and ventilation for airway protection • Treat hypotension, hypovolemia, and hypoxia • Focused neurological exam • Secondary survey and AMPLE history

Continued

Continued

Severity of TBI	*Mild TBI*		*Moderate TBI*	*Severe TBI*
Diagnostic	• CT scanning as determined by head CT rules • Blood/Urine EtOH and toxicology screens	• CT not available, CT abnormal, skull fracture • Significant intoxication (admit or observe)	• CT scan in all cases • Evaluate carefully for other injuries • Type and crossmatch, coagulation studies	• CT scan in all cases • Evaluate carefully for other injuries • Type and crossmatch, coagulation studies
Secondary management	• Serial examination until GCS is 15 and patient has no perseveration or memory deficit • Rule out indication for CT	• Serial examination Perform follow-up CT scan if first is abnormal or GCS remains <15 • Repeat CT (or transfer) if neurological status deteriorates	• Serial examination • Consider follow-up CT in 12–18 hours	• Serial examination • $PaCO_2$ 35–40 mm Hg • Mannitol • Brief hyperventilation $PaCO_2$ no <25 mm Hg • $PaCO_2$ no <25 mm Hg, except with signs of cerebral herniation. Avoid hyperventilation in the first 24 hours after injury when cerebral blood flow can be critically reduced. Emergent neurosurgical care
Disposition	Home if patient does not meet criteria for admission	• Obtain neurosurgical evaluation if CT or neurological exam is abnormal or patient status deteriorates • Arrange for medical follow-up and neuropsychological evaluation	Repeat CT immediately for deterioration and manage as in severe brain injury	
Perform ABCDEs in all patients with special attention to hypoxia and hypotension.				

(ABCDE: airway, breathing, circulation, disability, exposure; AMPLE: allergies, medications, past medical history, last eaten, events leading; CSF: cerebrospinal fluid; CT: computed tomography; EtOH: ethyl alcohol; GCS: Glasgow coma scale; $PaCO_2$: partial pressure of carbon dioxide; TBI: traumatic brain injury)

CHAPTER

Neck Trauma

Lokendra Gupta, Atul Singh Tomar

INTRODUCTION

Neck trauma management in emergency is a challenging and arduous task. Traumatic neck injuries account for 5–10% of all traumatic injuries and carry a high rate of morbidity and mortality because several vital structures can be damaged as this anatomical region contains many vital structures (complex network of neurovascular and muscular structures supported by various fascial planes). In the neck, multiple vital structures are vulnerable to injury in a small anatomic area and not protected by bones. These patients will require urgent initial assessment as per the advanced trauma life support (ATLS) protocol. The mortality rate for penetrating neck injuries is as high as 10%. The most common cause of death from penetrating neck trauma is a vascular injury. The area of highest risk is to injuries at the base of the neck, in zone 1. Beware that up to 50% of gunshot wounds are accompanied by significant injuries. These carry a mortality rate of 10–15%. Stab wounds cause serious injury in 20–30% of cases, with an overall mortality rate of 5%. The most common cause of delayed mortality is due to esophageal injury, which may not be readily apparent on initial presentation.

ETIOLOGY

Blunt: Motor vehicle accidents, sports injuries, strangulation blows

Penetrating: Stab injuries (knife, razor, blade, glass, etc.), projectile injuries (handgun, rifle, shotgun)

Note: Children may sustain penetrating injuries after falls onto objects in their environment (e.g., fence posts) or objects held in their mouth (e.g., toothbrushes or pencils).

ANATOMY

The neck is divided into three zones: (1) Zone 1, (2) Zone 2, and (3) Zone 3 (**Table 1**). In penetrating trauma, zone designations have anatomic, diagnostic, and management implications. Since the zone system is helpful in guiding management decisions, it is preferable to employ the zone system when describing traumatic injuries. Understanding the anatomy of the neck, especially the location of important structures, is essential to providing optimal care (**Fig. 1**).

TABLE 1: Anatomical zones of the neck and their structures.

	Zone 1	***Zone 2***	***Zone 3***
Anatomic landmarks	Clavicle/sternum to cricoid cartilage	Cricoid cartilage to the mandible	Superior angle of the mandible
• Anatomic structures in zone	• Proximal common carotid artery • Subclavian artery • Vertebral artery • Lung apices • Trachea • Thyroid • Esophagus • Thoracic duct • Spinal cord	• Carotid artery • Vertebral artery • Jugular vein • Pharynx • Trachea • Esophagus • Larynx • Vagus nerve • Recurrent laryngeal nerve • Spinal cord	• Vertebral artery • Distal carotid artery • Distal jugular vein • Salivary and parotid glands • Cranial nerves IX–XII • Spinal cord

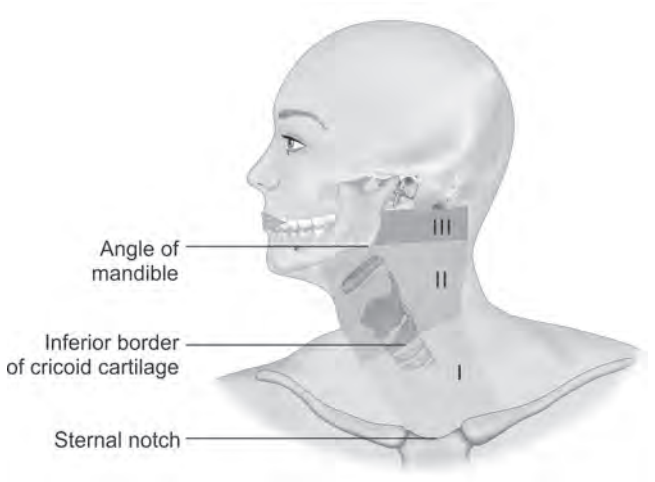

FIG. 1: Anatomical zones of the neck.

Zone 1: This is the area between the clavicles and the cricoid cartilage. This zone contains vital structures which include the innominate vessels, the origin of the common carotid artery, the subclavian vessels and the vertebral artery, the brachial plexus, the trachea, the esophagus, the apex of the lung, and the thoracic duct. Furthermore, surgical exposure and access can be difficult in this zone, because of the presence of the clavicle and bony structures of the thoracic inlet.

Zone 2: This is the area between the cricoid cartilage and the angle of the mandible. The following structures are located here: The carotid and vertebral arteries, the internal jugular veins, the trachea, and the esophagus. This zone has comparatively easy access for clinical examination and surgical exploration. It is the largest zone and the most commonly injured in the neck.

Zone 3: This is the area between the angle of the mandible and the base of the skull. This area contains the distal carotid and vertebral arteries and the pharynx. Since it is very close to the base of the skull, this area is less amenable to physical examination and difficult to explore during surgical evaluation.

Other important anatomic features are as follows:

- There is anatomic continuity in the fascial layers between the neck and the anterior mediastinum.
- The *platysma muscle* sits between the superficial and the deep cervical fascia: Violation of the platysma increases the likelihood of deep structure injury and should be explored in the operating room immediately.

Anatomically, the neck is also described in triangles. The sternocleidomastoid muscle separates the neck into two triangles: (1) The anterior triangle contains most of the major anatomic structures of the neck including larynx, trachea, pharynx, esophagus, and major vascular structures and (2) the posterior triangle contains muscles, the spinal accessory nerve, and the spinal column.

PATHOPHYSIOLOGY

The pathophysiology of neck injury depends on the mechanism of injury. The neck contains many critical organ systems adjacent to one another. It is for this reason that even innocuous-appearing wounds have the potential to cause either immediate or delayed life-threatening injuries or complications. It is rare to have a cervical injury without a neurological deficit in patients with penetrating neck trauma. With a low-risk National Emergency X-radiography Utilization Study I (NEXUS I) criteria, spinal cord injuries are unlikely to occur. These criteria obtain only if the patient is:

- Alert and awake
- Not intoxicated
- Has no signs or symptoms of neurologic injury
- Has no spinous process tenderness

Vascular injuries are the most common of cervical injuries and occur in up to 40% of patients with penetrating neck trauma.

CLINICAL PRESENTATION

Clinical presentations related to neck trauma are given below. An emergency medicine clinician must be familiar with hard and soft signs (**Table 2**). In pediatrics, it is prudent to consider *stridor* as an additional *"hard"* sign as it may indicate impending airway loss secondary to bleeding into the airway or from swelling encroaching on the patency of the airway. A patient with an apparently stable airway, in the first few hours, may deteriorate quickly due to edema. Even minor signs should still lead to very careful observation.

- ***Airway*:**
  - Respiratory distress
  - Stridor hoarseness
  - Hemoptysis
  - Subcutaneous emphysema
  - Sucking wound
- ***Vascular:***
  - Hematoma
  - Change of sensorium
  - Persistent bleeding
  - Bruit

TABLE 2: Clinical features of concern in neck trauma.

Hard signs	• Airway compromise • Expanding and pulsatile hematoma • Active, brisk bleeding • Hemorrhagic shock • Hematemesis • Neurologic deficit • Massive subcutaneous emphysema • Air bubbling through wound
Soft signs	• Hemoptysis • Oropharyngeal blood • Dyspnea • Dysphagia • Dysphonia • Nonexpanding hematoma • Chest tube air leak • Subcutaneous or mediastinal air • Vascular bruit or thrill • Crepitus

- Thrill
- Hypovolemic shock

- ***Neurological*:**
  - Hemiplegia
  - Quadriplegia
  - Coma
  - Cranial nerve deficit
  - Change of sensorium
- ***Esophageal*:**
  - Dysphagia
  - Odynophagia
  - Hematemesis
  - Hemoptysis
  - Tachycardia
  - Fever

EVALUATION OF NECK TRAUMA

Evaluation of neck injuries warrants notification of a trauma team or surgeon, if either is available. Since physical examination may not be reliable in ruling out injuries in patients with neck trauma, one should consider a low threshold for obtaining additional imaging studies and/or a surgical consultation. Periodic examination is required to identify deterioration in clinical status as well as any ongoing. The value of a thorough secondary survey to evaluate for additional injuries cannot be overemphasized in such patients. Diagnostic testing is performed for stable patients manifesting soft signs of injury and sometimes even for those who are asymptomatic at initial presentation.

A plain chest X-ray may show pneumomediastinum/pleural effusion/hydrothorax/subcutaneous emphysema in the event of esophageal perforation. *A plain X-ray of neck* (*soft tissue views*) may show surgical emphysema and soft-tissue swelling but are unreliable in demonstrating laryngeal injury.

Computed tomography (CT) angiogram of neck shows that the role of screening for associated cerebrovascular injury to carotid or vertebral arteries is limited in the pediatric population. *Indication for CT angiogram of neck in trauma includes*: Lateralizing neurological deficit (not explained by CT of head), infarct on CT of head, cervical hematoma, massive epistaxis, anisocoria/Horner's syndrome, Glasgow Coma Scale (GCS) < 8 without significant CT head findings, and cervical spine fracture. Base of skull fracture (particulary fracture extending through petrous temporal bone and involving carotid canal). Facial fractures (particularly LeFort I or III). A plain CT scan of neck, i.e., without contrast, may be better able to identify laryngeal fracture but should not be performed in unstable patients.

Contrast Swallow

Ear, nose, and throat (ENT) may advise a contrast study, but this investigation should not be ordered without ENT consultation. Water-soluble contrast, if swallowed prior to X-ray, may reveal a contrast leak. Barium contrast can cause mediastinal and/or pulmonary inflammation if aspirated, so it is better avoided if there is an aspiration risk.

All patients with signs/symptoms of injury to the neck should be discussed with ENT for consideration of a fiberoptic laryngoscope.

Evaluation of Aerodigestive Tract Injuries

Aerodigestive tract injuries, especially those involving the cervical esophagus, should be identified and repaired within 12–24 hours after injury to minimize associated morbidity and mortality. Evaluation of asymptomatic aerodigestive tract injuries includes contrast swallow studies and endoscopy (rigid and flexible esophagoscopy, bronchoscopy, and laryngoscopy).

- ***Endoscopy*:** It is more reliable than contrast swallow studies to identify injuries to the hypopharynx and cervical esophagus. Several authors have demonstrated that endoscopy will identify 100% of digestive tract injuries, whereas contrast swallow studies are less sensitive, especially for hypopharyngeal injuries.
- ***Rigid and flexible esophagoscopy, rigid and flexible bronchoscopy, and rigid direct laryngoscopy*:** These are performed in the operating room under general anesthesia. It is recommended that both rigid and flexible esophagoscopy be performed to rule out occult esophageal injuries.
- ***Rigid and flexible esophagoscopy*:** Rigid esophagoscopy may provide a better view of the proximal esophagus near the cricopharyngeal muscle, while flexible esophagoscopy, with its magnification on the viewing screen and ability to insufflate, gives excellent visualization of more distal esophageal anatomy.
- ***Swallow studies*:** Finally, swallow studies with either gastrografin or barium may not be available in austere environments to rule out occult esophageal injuries and, as noted above, are less accurate than endoscopy. Missed esophageal injuries, which may be occult in 25% of patients, can be devastating, with mortality rates ranging up to 25%.

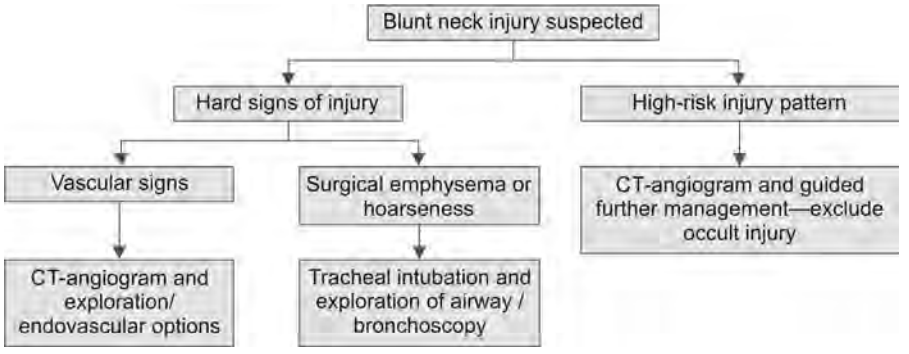
MANAGEMENT

Since the neck contains vital structures, prompt evaluation and rapid intervention are required. The initial assessment should be performed according to the ATLS protocols. An immediate trauma service consultation should be obtained for patients with suspicion of vascular, tracheal, or esophageal injury.

Priorities in the management of patients with neck trauma are like those for any other patient with a life-threatening condition. The primary priorities are securing the airway, maintaining ventilation, controlling hemorrhage, and treating shock. At the same time, check vital signs and determine the stability of the patient. Patients with neck may have other life-threatening injuries that may take precedence. Further management of blunt neck trauma and penetrating neck trauma is described in **Flowcharts 1** and **2**, respectively.

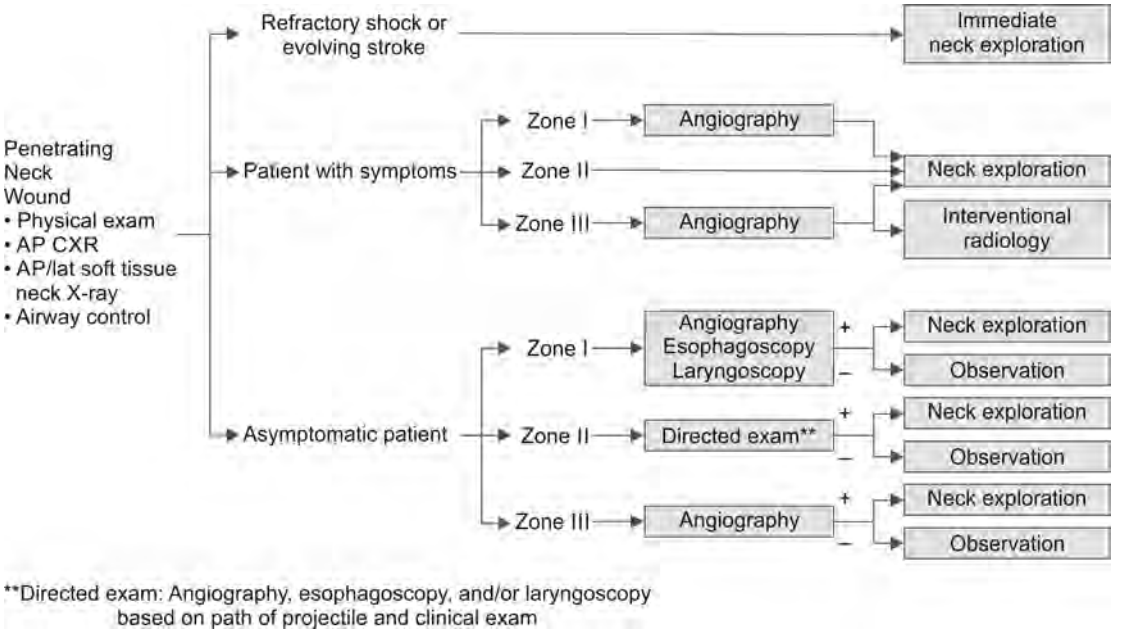
Airway

As always, the priority is airway stabilization, particularly in patients with neck trauma, while maintaining cervical spine immobilization. Remember that in-line stabilization should always be maintained when there is a concern for a cervical spine injury. Up to 10% of patients with penetrating neck injuries may present with airway compromise. Be aware that despite a stable initial appearance, airway compromise can ensue rapidly.



Blunt neck injury suspected
Hard signs of injury
High-risk injury pattern
Vascular signs
Surgical emphysema or hoarseness
CT-angiogram and guided further management—exclude occult injury
CT-angiogram and exploration/ endovascular options
Tracheal intubation and exploration of airway / bronchoscopy

FLOWCHART 1: Management of blunt neck trauma.



(AP: anteroposterior; CXR: chest X-ray)

FLOWCHART 2: Management of penetrating neck trauma.

Beware that swelling, distorted anatomy, and hematoma formation may contribute to impending airway obstruction in facial or neck trauma. Therefore, early airway control should be considered as the conditions may rapidly worsen.

Breathing

Evaluate the breathing and assess for any hemothorax or pneumothorax, particularly with penetrating zone 1 injuries.

Circulation

Direct simple pressure on the open wounds should be used to control bleeding in the emergency department. Wounds that have air sucking or bubbling should be covered with Vaseline gauze. No blind probing of the wound and no clamping of the vessels should occur in the emergency department. It is important not to occlude both carotid arteries or obstruct the patient's airway. Avoid nasogastric tube placement in patients with penetrating neck injury because of the risk of hematoma rupture. The agitation of the patient during tube insertion may precipitate bleeding. Further management of the patient with penetrating neck trauma depends on the anatomic zone of injury, clinical presentation, and hemodynamic stability. Determine the zone of injury, as this will determine evaluation and management strategy.

Zone 1: Since up to one-third of patients with a clinically significant zone 1 injury may have no symptoms at their initial presentation, many centers advocate vascular evaluation of the aortic arch and great vessels, with an esophageal evaluation.

Zone 2: This area has easier surgical access and poses a low risk for adverse sequelae from exploration. The decision for surgical exploration depends on the symptoms. Symptomatic penetrating zone 2 injuries should undergo neck exploration. Asymptomatic patients with penetrating zone 2 injuries may be treated with either mandatory exploration or directed evaluation and serial examinations. *Indications for an angiogram:* A stable patient with persistent hemorrhage or neurologic deficits, the presence of Horner syndrome (sympathetic nerve plexus injury), and hoarseness (recurrent laryngeal nerve injury). This suggests a violation of the carotid sheath.

Zone 3: In this zone, there is potential for injury to major blood vessels and the cranial nerves close to the skull base. Beware that patients with arterial injuries may be asymptomatic at their initial presentation, and surgical exposure and control of bleeding in this location may be quite difficult. In addition, many vascular injuries are amenable to definitive treatment by an interventional radiologist. Therefore, the injury can be potentially treated in the same setting like the one in which the diagnostic angiogram is done.

SUMMARY

Initial management of these patients is established according to ATLS criteria. Urgent surgical examination is indicated in unstable patients and patients with severe signs. Later, they may benefit from previous CT angiography. If hemodynamic instability is caused by hemorrhage, tamponade with a Foley catheter can assist in the initial stabilization of the patient, providing the necessary time to perform a CT angiogram and diagnose the injury type. It is advisable to perform CT angiogram in all symptomatic patients (reducing the need for surgical examinations, as well as their complications) and also in asymptomatic patients with a high-speed mechanism of injury. Observation is safe in asymptomatic patients; those with a negative CT angiogram do not require treatment. Angiography and interventional radiology can be diagnostic and therapeutic tools in patients with vascular trauma, thereby avoiding unnecessary surgical interventions.

Overall, injuries to zone 1 have the highest morbidity and mortality. Zone 2 injuries are the most common after penetrating trauma, but because they can be readily accessible, they also have the best prognosis. Injuries to Zone 2 can be challenging, because access to some structures may not be easy. The prognosis of these injuries is guarded. In individuals who suffer complete transection of the spinal cord, the injury is almost always fatal. Individuals who do retain neurological function, including preservation of rectal tone, usually have a good outcome. However, if the neurological deficits persist, the outcomes are poor. When the vasculature structures are injured by blunt trauma, the outcomes are worse compared to penetrating injuries. In many neck injuries, one also has to search for airway and esophageal injuries as they may not always be apparent. Overall, the mortality rate for patients suffering penetrating trauma to the neck varies from 2 to 5%, but if a major blood vessel has ruptured, this is often fatal in about 70% of cases.

The *laryngotracheal airway* and the *cervical spine* are the two most integral structures that can be damaged in blunt trauma to the neck. Prior to any intervention, such as flexible fiberoptic evaluation of the airway, the neck must be stabilized securely in line. The status of the cervical spine takes evaluative precedence after the airway has been secured in a manner that does not compromise a potential cervical spine injury. Hemodynamic stability or instability will be an important guide to the urgency of intervention, including diagnostic computed tomography angiography (CTA) prior to exploration of the neck to control bleeding and secure the vascular elements. An excellent physical examination must always be performed and will be the clinical guide to the next steps in evaluation and treatment.

IMPORTANT POINTS

- Penetrating injuries to the neck can damage a host of structures. Understanding the zones of the neck and the structures within them can help predict injuries.
- If the platysma is violated, it should be assumed that deeper structures have been injured until proven otherwise.
- Early airway management is crucial as injuries can lead to dynamic airway obstruction. Always be prepared for a surgical airway.
- The presence of any hard signs of aerodigestive/neurovascular injuries (expanding/pulsatile hematoma, active brisk bleeding, hemorrhagic shock, massive subcutaneous emphysema, air bubbling through the wound, neurologic deficit) or violation of platysma mandates an immediate operation theater (OT) trip. Do not delay the patient in getting to the OT for additional studies.
- Attempt to control vascular injuries with direct pressure and consider balloon tamponade with a Foley catheter.

225
CHAPTER

Spinal Trauma

Winston Noronha

INTRODUCTION

Spinal cord injuries (SCIs) are seen in high-speed vehicle crashes and falls from heights. The victims are usually young, healthy adult males. Up to 10–15% of head injury cases have a coexisting cervical spinal injury, so radiological evaluation of the cervical spine is necessary along with head injury. During the evaluation of head injury, there should be high suspicion of spinal injury and adequate immobilization of spine should be maintained. Proper evaluation and management of spinal injurers are important because if missed or not treated, they can lead to permanent neurological deficit. There is often injury to the brain, chest, abdomen, pelvis, and extremities. SCI can occur at any level and it can be complete or incomplete. The most common level of SCI in adults is C5, followed by C4, C6, C7, T12, and L1. In children, fractures of C1 and C2 are more common. SCI primarily affects young, healthy adults—mostly young, adult males (80.7% male predominance)—and thus is a devastating and life-altering injury. SCI can present in the form of minor symptoms such as pain, numbness to severe symptoms such as paralysis and incontinence. Injury to any one of the seven cervical vertebrae can cause quadriplegia (injury at the level of neck) (**Fig. 1**). Quadriplegia and paraplegia have high mortality and morbidity due to bedsores, respiratory and urinary infection, contractures, etc. SCIs do not only damage the sensory and motor systems but also cause muscle atrophy, pressure sore, kidney, bladder and bowel problems, and cardiac and respiratory dysfunctions. These patients need constant long-term care which throws a great burden on the family financially, psychologically, and physically.

APPLIED ANATOMY OF SPINE

The vertebral column has 33 vertebrae extending from the skull base to the coccyx. There are 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4–5 coccygeal vertebrae. The vertebrae are separated by disks. The spinal canal contains the spinal cord, which is protected in front by the vertebral body and behind by the laminae, pedicles, transverse and spinous processes, and strong ligaments and muscles. The spinal canal is widest at the level of second cervical vertebra and narrows below. Various nerve roots exit the spinal cord at each vertebral level through fenestrations. The vertebral column is strong enough to protect the delicate spine but has enough flexibility to allow full range of spinal movement (flexion-extension, lateral flexion, and rotation). The cervical spine by its location and greater mobility makes it most

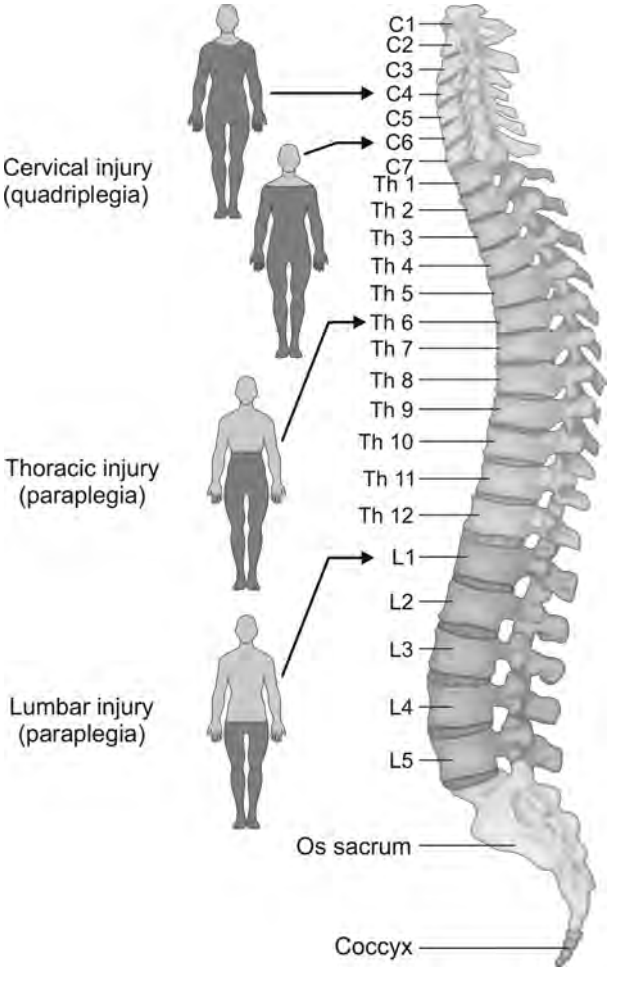

FIG. 1: Level of spinal injury and manifestation.

vulnerable to injury. Thoracic vertebrae have limited mobility and these are supported by the rib cage which makes them less vulnerable to injuries. The thoracolumbar junction between the less mobile thoracic and more mobile lumbar vertebrae is more prone to injuries. A typical vertebra consists of: Body, pedicles, laminae, transverse and spinous processes, and four articular surfaces (**Fig. 2**). The bones are held by tough ligaments, i.e., anterior and posterior longitudinal ligaments (PLLs) and the posterior ligamentous complex (PLC) which includes supraspinous and interspinous ligaments, ligamentum flavum (LF), and capsules of the facet joints. In children, the spinal cord can be injured without vertebral fracture. This is called *SCIWORA* (Spinal Cord Injury without Radiological Abnormality). Ligamentous injuries can also cause spinal cord damage without vertebral fractures. In the spinal tract, the nerve fibers are arranged in columns or tracts (**Fig. 3**). The important ones are mentioned in **Table 1**.

MECHANISMS OF INJURY

Various mechanisms of hyperflexion, hyperextension, flexion rotation, and penetration give rise to various injuries to the spine (**Fig. 4**):

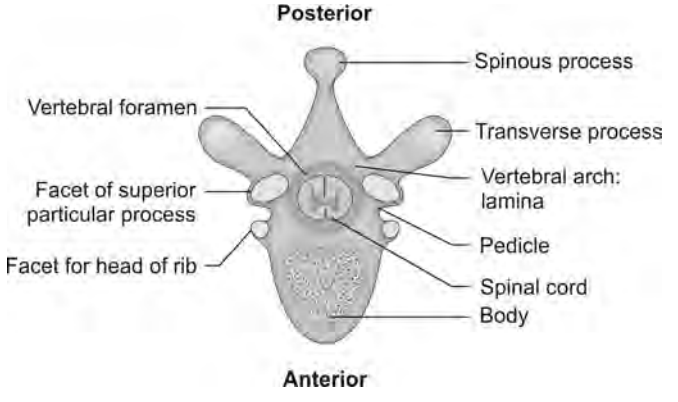

FIG. 2: Typical vertebra.

- Compressive force in a craniocaudal direction (axial loading)
- Acute flexion causing anterior wedge compression of the vertebra
- Flexion around an axis anterior to the vertebral column—transverse vertebral chance fracture
- Disruption of the posterior spinal elements (pedicles, facets, and lamina)—fracture-dislocation

CLASSIFICATION OF SPINAL INJURIES

Level of Injury

The level of injury is documented by the vertebral level and neurological level. More important is the neurological level which may not correspond to the bony level as the nerves ascend to join the cord higher up.

Severity of Neurological Deficit

Neurological deficit leads to complete or incomplete quadriplegia/tetraplegia and complete or incomplete paraplegia. Incomplete refers to the presence of some voluntary motor activity such as toe movement, sacral sparing, or sensation below the level of the lesion.

Morphology

It is categorized as fractures, fracture-dislocations, SCIWORA, and penetrating injuries. It is further classified as stable and unstable.

Specific Syndromes

Anterior cord syndrome results from an ischemic injury to the anterior part of the cord and has a poor prognosis. Motor pathway damage leads to paraplegia with loss of pain and temperature bilaterally due to damage to the anterior spinothalamic tract. Position and vibration sense are preserved. *Central cord syndrome* occurs in the elderly due to falling forward and striking the face or chin. There is flexion followed by hyperextension. The deficit is more in the upper limbs than

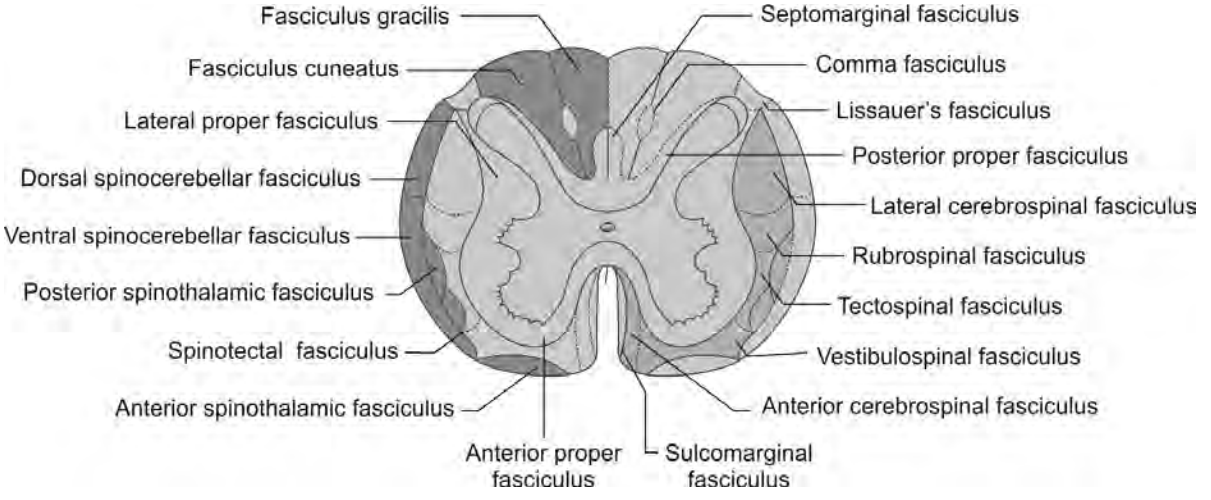

FIG. 3: Spinal tract (transverse section).

the lower limbs. Prognosis is good and recovery occurs first in the lower limbs, then the bladder, and finally the upper limbs. *Brown-Sequard syndrome* is rare and occurs due to the hemisection of the cord. It most commonly occurs following penetrating injury. There is loss of motor power and position and vibration sense on the same side and contralateral to the loss of pain and temperature.

TABLE 1: Spinal tract (location, function, testing).

Tract	*Location*	*Function*	*Testing*
Corticospinal	Anterolateral	Motor power on the same side	Voluntary muscle contraction/ involuntary response to pain
Spinothalamic	Anterior and lateral	Pain and temperature from the opposite side	Pinprick
Posterior columns	Posteromedial	Position sense and vibration sense from the same side	Position of finger and toes Tuning fork

Primary and Secondary Spinal Cord Injury

Primary injury occurs due to the initial mechanical forces and fractured bone fragments, disk materials, and/or ligaments which injure the cord. *Secondary injury* occurs due to movement of the spine, hypotension, and hypoxia. There are physiologic, extracellular biochemical, and intracellular changes. Ischemia can be the result of either capillary or arterial occlusion. The blood–spinal cord barrier integrity is lost leading to an influx of cytokines, vasoactive peptides, and peripheral inflammatory cells leading to cord edema and the proinflammatory state. Neurons are disrupted, and there is excess of extracellular glutamate concentration leading to excitotoxic cell death. Cells die leading to numerous cytotoxic byproducts [e.g., adenosine triphosphate (ATP), potassium ions, deoxyribonucleic acid (DNA), free radicals] released into the local microenvironment which further propagate cell death.

CLINICAL GRADING

Spinal cord injuries are graded according to the *American Spinal Injury Association (ASIA)* scale. The likelihood of recovery increases from category A to D; complete injury carries the worst prognosis.

ASIA A: Injury is complete with no sensory or motor function.

ASIA B: A sensory incomplete injury with complete motor function loss.

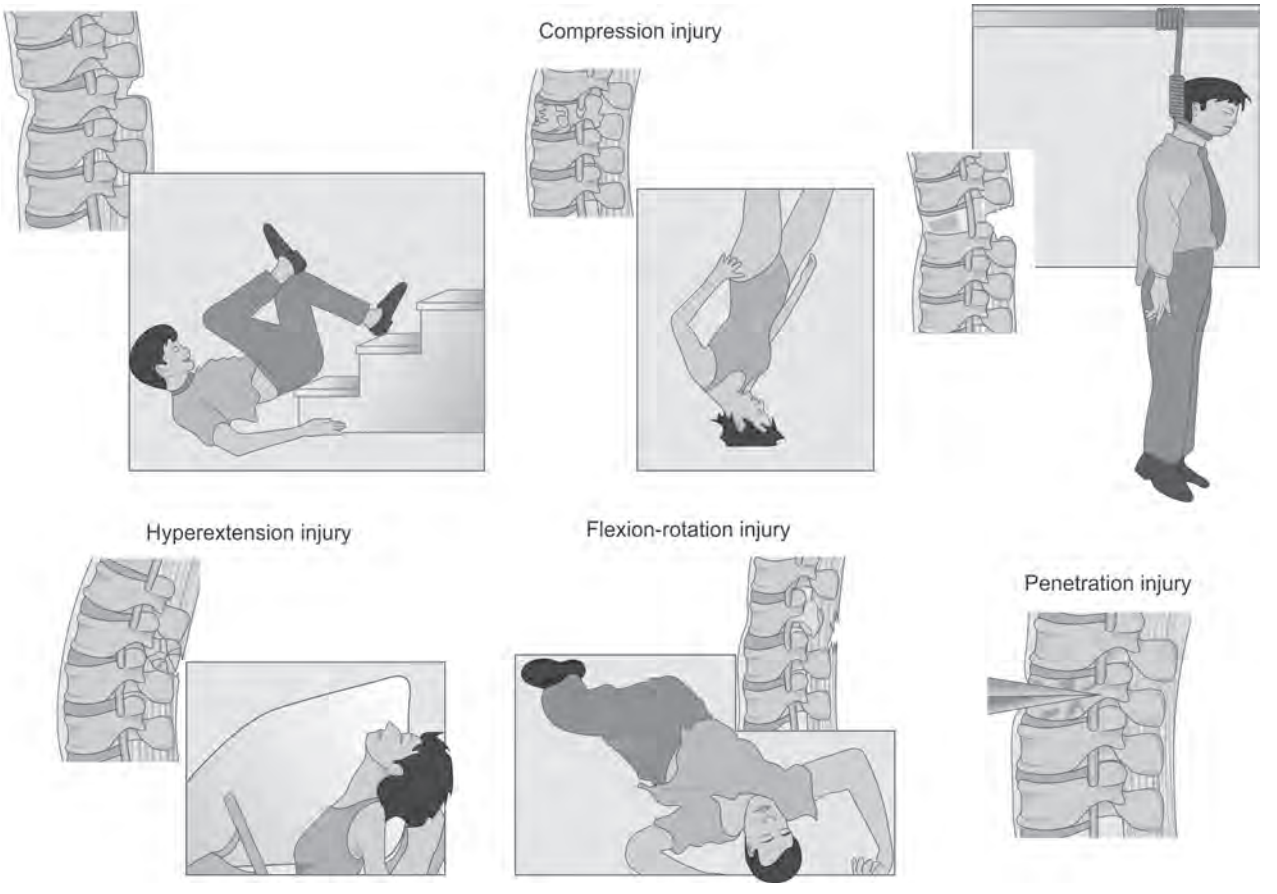

FIG. 4: Mechanism of spinal cord injury.

ASIA C: A motor incomplete injury, where there is some movement, but less than half the muscle groups are antigravity.

ASIA D: A motor incomplete injury with more than half of the muscle groups being antigravity.

ASIA E: Normal

SPECIFIC INJURIES

Upper Cervical Injuries

This type of injury includes injuries to the base of the skull, C1 and C2. Cervical spine injuries are less common in children, but the upper levels are more likely. Mechanisms can be flexion, extension, lateral bending, rotation, and axial loading. *Atlanto-occipital dislocation* is seen in shaken baby syndrome, which occurs due to distraction and extension. It is highly unstable with high mortality as ligaments holding the skull to C1 and C2 are torn. On lateral radiographs, the distance between the clivus and the odontoid is >5 mm. Traction is avoided and treated by occipital cervical fusion. *Disruption of the transverse ligament* of C1 is seen in the elderly due to flexion injury. In complete disruption, the atlanto dens distance is >5 mm and C1/C2 fusion is indicated. *Atlas (C1)* bilateral posterior arch fractures are stable and treated with orthosis. They occur due to compression and extension. They can be associated with fracture of Dens. Fractures on one side of the lateral mass involve anterior and posterior arches due to compression with lateral bending. *Jefferson's fractures* occur due to axial compression and are four-part fractures, i.e., bilateral anterior and posterior arch fractures (**Fig. 5**). Lateral mass and Jefferson's fractures can produce retropharyngeal swelling and respiratory obstruction and may need prophylactic intubation. If there is no lateral widening, an orthosis is used. If the intermass widening is <6.9 mm, a halo can be used, but if it is >6.9 mm, then traction for reduction is followed by halo. *The odontoid process* is the peg-shaped protuberance from the atlas which projects through the ring of the axis. It is commonly fractured and seen on open-mouth views and computed tomography (CT) scans. *Anderson and D'Alonzo* have classified odontoid fractures into three types (**Fig. 6**). (1) Type I fractures are through the dens above the waist and are treated conservatively. (2) Type II fractures at the junction of the dens and body are unstable. If there is <5 mm displacement or <10° of tilt, then halo is enough, but if displacement is >5 mm or tilt is >10°, fixation with a screw or C1/C2 fusion is needed. (3) Type III extends from the dens to the body, heal spontaneously, and do not need surgery. *Hangman's fracture* is a fracture of the posterior elements of C2 and occurs due to sudden extension. *Levine and Edwards* classified the fractures into Types I, II, IIA, and III.

Type I fractures are stable since only the posterior arch is broken with minimal displacement and treated by orthosis. Type II fractures cause anterior displacement of C2 over C3 through the disk, the PLL being intact, and are treated by traction and halo. In Type IIA, the PLL is also disrupted. These are unstable and traction is contraindicated, treated by halo. Uncommon are Type III fractures with the arch fractured and facets remaining attached to the body. There is bilateral facet dislocation, they have no neurological deficit, but need fixation to maintain stability. *C1 rotary subluxation* occurs in children and presents as torticollis. It occurs following trauma, respiratory infection, or rheumatoid arthritis.

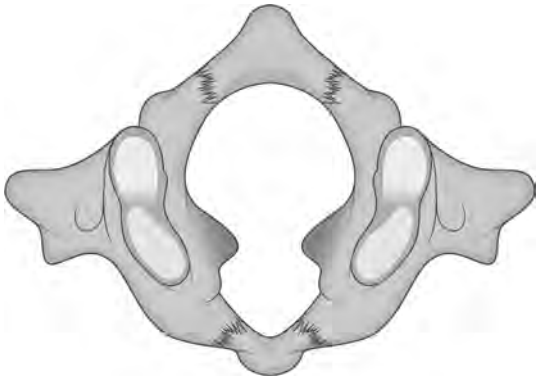

FIG. 5: Jefferson fracture.

Lower Cervical Spine Injuries

Neurological deficit is common as the canal is narrow. The diaphragm may also be paralyzed leading to respiratory distress. *Facet dislocation:* Unilateral dislocations may cause nerve root compression while bilateral dislocations present with neurological deficits and need early magnetic resonance imaging (MRI). Reduction with traction is done followed by fusion. *Compression fractures* are stable when PLC is intact and treated by orthosis; otherwise, fusion is done. Burst *fractures* occur due to flexion with compression. Stable fracture with intact neurology can be managed nonoperatively by applying halo vest for immobilization of spine. Unstable fracture can be managed by posterior fusion with halo vest. If there is neurological damage, then anterior corpectomy with fusion and halo is done, whether stable or not. If it is unstable, then posterior fusion is added. *Teardrop fractures* are unstable, arise due to flexion with rotation and compression, and treated with posterior fusion and halo application. Where neurologic injury exists, anterior corpectomy and fusion are added.

FIG. 6: Anderson and D'Alonzo classification of odontoid fractures: Type I, Type II, Type III.

Thoracolumbar Spine

Thoracolumbar spine prone for wedge compression, burst fracture, Chance fracture, and fracture with dislocation (**Table 2**). *Major injuries* include compression fractures, burst fractures, flexion-distraction injuries, and fracture-dislocations. *Minor injuries* include fractures of transverse, spinous, and articular processes and of pars interarticularis. Transverse process injuries may have brachial or lumbosacral plexus injuries associated with them. *Compression fractures* can be anterior or lateral and are seen on lateral and antero-posterior (AP) views, respectively, due to anterior and lateral flexion forces (**Fig. 7**). These are stable injuries, rarely present with neurological deficits, and are treated with a hyperextension brace. Regular radiographs are essential to monitor for loss of height and angulation. >50% compression may indicate injury to PLC and instability. Nowadays, minimally invasive kyphoplasty can be done by injecting methyl methacrylate. *Burst fractures* caused by vertical and axial compression can impinge on the cord producing neurological deficits (**Fig. 8**). When the posterior ligaments are intact and there is no neurological deficit, they can be managed with a brace. But when there are signs of neurological deficit or PLC is affected, decompression and internal fixation are done. *Chance fractures* are transverse fractures through the body and occur due to flexion most commonly with an incorrectly placed seatbelt (**Fig. 9**). These fractures are commonly associated with other injuries to the retroperitoneum or intra-abdominal viscera. *Fractures with dislocations* are uncommon and occur due to a combination of flexion, rotation, and distraction forces. Since the canal is narrow, they present with neurological deficits. All three columns are affected, and these fractures are unstable. Treatment is reduction followed by stabilization by a posterior approach. An anterior approach may be added if thecal sac compression is persistent.

TABLE 2: Types of spine fracture.

Fracture	*Column affected*	*Stable/Unstable*
Wedge	Anterior only	Stable
Burst	Anterior and middle	Unstable
Fracture dislocation	Anterior, middle and posterior	Unstable
Seat belt	Anterior, middle and posterior	Unstable

Denis Three-column Concept of Spinal Fracture

Three-column concepts are applied mainly for the classification of thoracolumbar spinal fracture but can also be

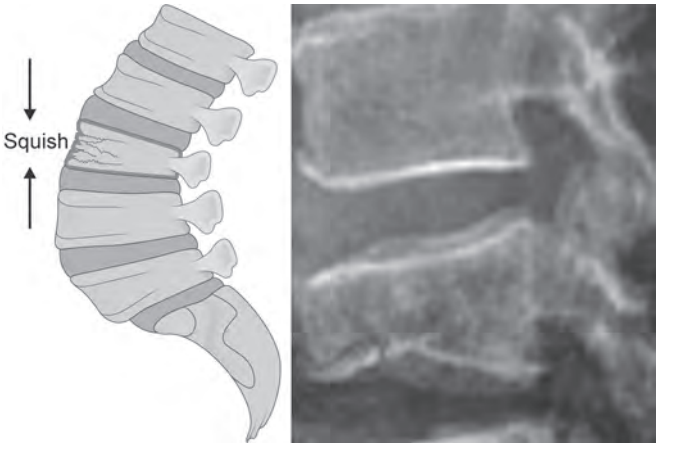

FIG. 7: Compression fracture.

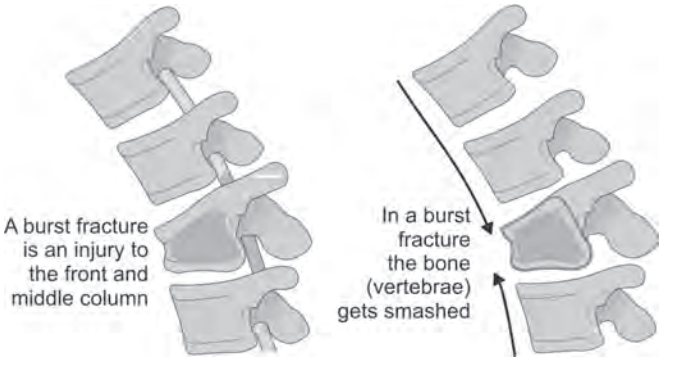

FIG. 8: Burst fracture.

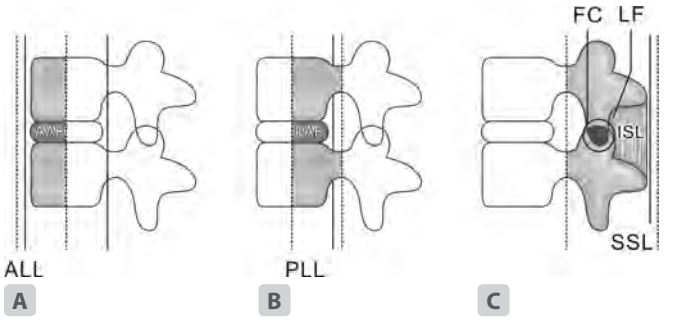
FIG. 9: Chance fracture occurring due to an incorrectly placed seatbelt.



(AAF: anterior annulus fibrosus; ALL: anterior longitudinal ligament; FC: facet capsule; ISL: interspinous ligament; LF: ligamentum flavum; PAF: posterior annulus fibrosus; PLL: posterior longitudinal ligament; SSL: supraspinous ligament)

FIGS. 10A TO C: Denis three-column concept of spinal fracture. (A) Anterior; (B) Middle; (C) Posterior.

applied to the lower cervical spine. These are widely used in clinical practice and for reporting due to their simplicity (**Figs. 10A** to **C**).

Anterior column—anterior longitudinal ligament (ALL), anterior two-thirds of the vertebral body, and annulus fibrosis or disk

Middle column—posterior third of the vertebral body and annulus fibrosis and PLL

Posterior column—pedicles, facet joints, capsules, laminae, supraspinous and interspinous ligaments, joint capsule, and LF

For instability, there should be a compromise of two columns, i.e., middle + anterior or middle + posterior.

RADIOLOGY IN SPINAL TRAUMA

Canadian C-spine rule and National Emergency X-Radiography Utilization Study (NEXUS) criteria are used for cervical spine radiology.

Canadian C-spine rule consists of the following:
- Age ≥ 65 years
- Paresthesias in extremities
- Dangerous mechanism of injury:
  - Fall from an elevation ≥3 ft or five stairs
  - Axial load to the head (e.g., diving)
  - Motor vehicle collision at high speed (>100 km/h) or with rollover or ejection
  - Bicycle collision
  - Collision involving a motorized recreational vehicle

  If any of these are present, imaging is done.

Nexus criteria: Spine imaging is recommended if one of the following criteria is present:
- Focal neurologic deficit
- Midline spinal tenderness
- Altered level of consciousness
- Intoxication
- Distracting injury

NEXUS Mnemonic: *N*—neurodeficit/*E*—ethanol (alcohol) intoxication/*X*—eXtreme distracting injury/*U*—unable to provide history (altered level of consciousness)/*S*—spinal tenderness (midline). Radiographs with AP and lateral views of the cervical spine will detect 90–95% of lesions. For C1, open-mouth view and for C7, swimmer's views are taken. The thoracic and lumbar spine can be preliminarily studied by radiographs and are taken in AP, lateral, and sometimes oblique views.

Computed tomography: Multiplanar CT scans with 3-mm fine cuts and sagittal 3D reconstruction are very useful for determining the bony injury, especially in lateral mass fractures, facet fractures, and fractures causing bony fragments to impinge on the spinal canal.

Magnetic resonance imaging: MRI is not usually done in the acute setting. It is useful to study the soft tissues, ligamentous injuries, hematomyelia, and cord contusions.

INITIAL ASSESSMENT AND MANAGEMENT

Patients are shifted with cervical collar and placed on a long spine board. They are logrolled during shifting without unnecessary movement to the spine. Two sandbags are placed on either side of the head to prevent neck rotation. First is *airway, breathing, and circulation.* During intubation, care should be taken to maintain in-line stabilization manually. The important aspect is to maintain oxygenation and blood pressure. Low blood pressure with tachycardia indicates hypovolemic shock, and radiographs of chest and pelvis and extended focused assessment with sonography for trauma (eFAST) are done to rule out sources of bleed.

Cervical Collar and Spine Board

After resuscitation, if the cervical spine has no injury, then the cervical collar is removed (**Fig. 11**). Traditionally, when any spinal injury has been suspected, the entire spine is immobilized onto a longboard, along with the placement of a rigid collar to immobilize the cervical spine. Spine boards (**Fig. 12**) can cause significant discomfort to the patient, skin breakdown, and decubitus ulcers in a relatively short amount of time. It can compromise ventilatory status in some patients. Thus, for all of these reasons, patients who are placed on a backboard initially should be removed from them as soon as possible. The backboard should continue to be used for specific purposes. It is an excellent device to help extricate patients or when patients need to be carried over large distances. The spine board is removed as early as possible or within 2 hours

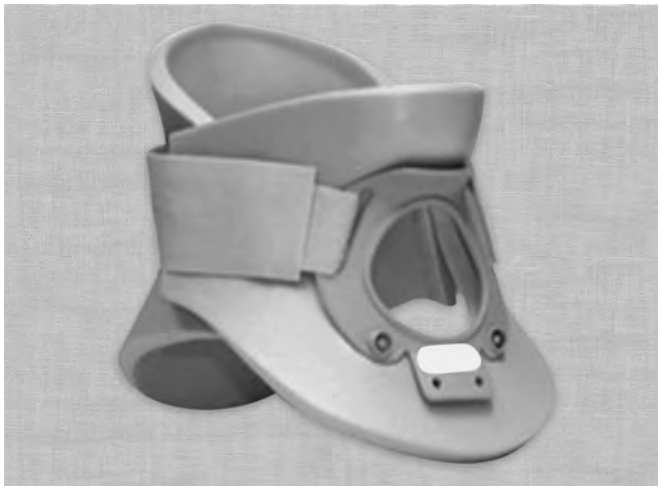


FIG. 11: Philadelphia cervical collar.

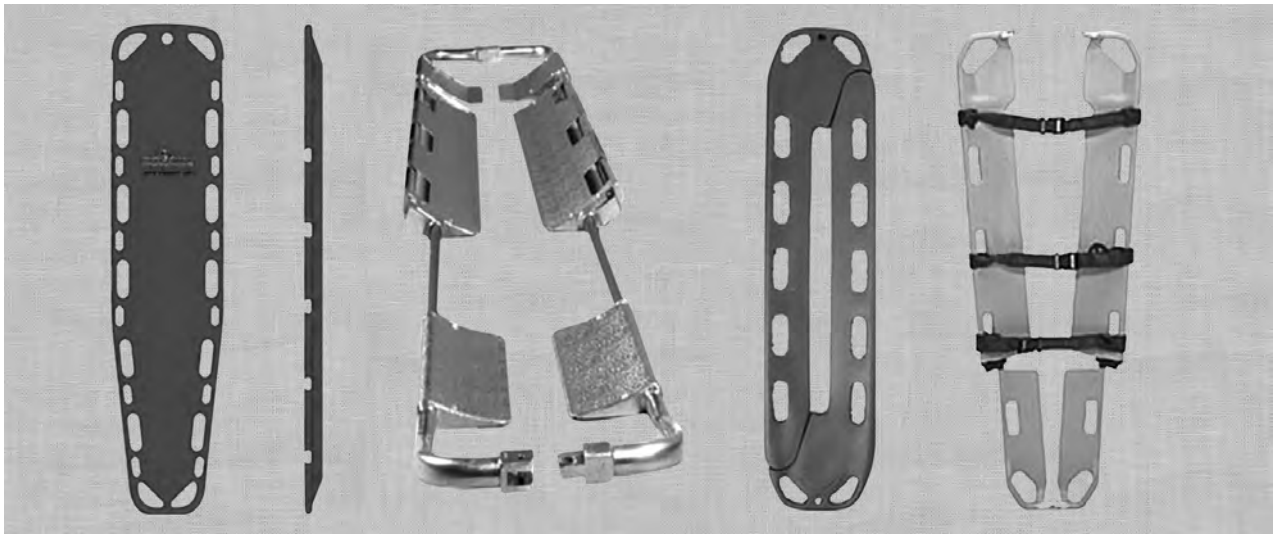

FIG. 12: Spine board, scoops, Combi-carrier, ortho-stretcher.

to prevent pressure sores. Neurological assessment is possible only in a conscious patient. Simultaneously, radiological assessment is also done.

Technique of Removal of Helmet

Two rescuers are involved in this process. The first rescuer maintains the in-line stabilization by placing both sides of the mandible and applying pressure on the jaw. The second rescuer slides the helmet backward if the helmet is covering the full face; glasses should be removed first and the helmet should be expanded laterally to clear the ears and moved backward and raised over the nose for soft removal (**Fig. 13**).

Technique of Logroll in Shifting Suspected Spinal Trauma

Logroll is the procedure used to put the injured on a stretcher. Four persons are required for this technique. Maximum care must be taken to avoid worsening an unstable trauma. The head-neck-chest axis must be kept straight to protect the spine, and the first responders must keep the patient's body stable (no movement of the feet) during the lift (**Fig. 14**).

Neurogenic Shock and Spinal Shock

Maintaining mean arterial pressure (MAP) at 85–90 mm Hg for 7 days has been found to improve outcomes. The presence of bradycardia with hypotension can be due to neurogenic shock while head injury produces hypertension and bradycardia. In SCI, there are two conditions: (1) *Neurogenic shock and* (2) *spinal shock*. Neurogenic shock is a cardiovascular event. It occurs when there is a cord injury above the T6 level. The sympathetic nerve gets affected and due to peripheral vasodilatation, there is hypotension. Patients cannot develop tachycardia as the sympathetic nerves to the heart are affected. This is treated with fluids followed by vasopressors, if necessary. *Spinal shock* is the state of complete paralysis due to spinal cord injury. There is flaccid paralysis with loss of reflexes including anal wink and bulbocavernosus reflex. This will recover as the neurological condition improves. SCI is often overlooked in (1) head injury, (2) intoxication, and (3) polytrauma initial.

FIG. 13: Helmet removal in suspected spine trauma.

Use of Steroids

The 2016 Cochrane review is recommended against the use of steroids. But the AO Spine 2017 guidelines recommend steroids, i.e., methylprednisolone intravenously within 8 hours of cervical spine injury and continued for 24 hours. The dose should be 30 mg/kg bolus followed by 5.4 mg/kg/h for 23 hours. An increased risk of sepsis (pneumonia, septicemia) was noted within 48 hours of steroid administration.

Evaluation of Neurological Status

Neurological assessment consists of (1) Glasgow coma scale, (2) pupils, and (3) localizing signs. The spine is examined during the secondary survey for deformity, bruising, and lacerations on inspection and tenderness, spasm, and step on palpation. Sensory level, motor level, and reflexes are examined.

Cranial nerve examination and reflexes: The lower four cranial nerves may be involved in high cervical spine injuries and should be tested. The reflexes which are assessed include

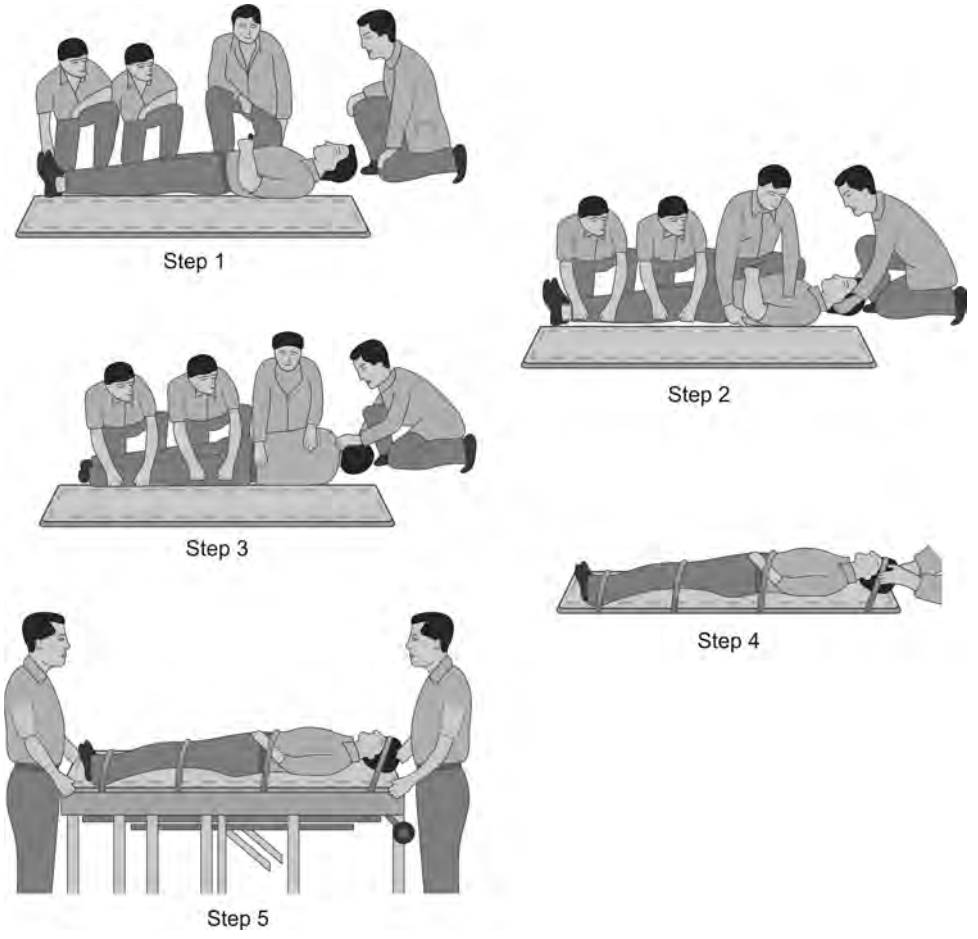

FIG. 14: Logroll techniques.

biceps (C5), triceps (C7), knee (L4), and ankle (S1) jerks. *Reflex grading (0–4) is as follows:* 0—absent reflex, 1—decreased, 2—normal**,** 3—exaggerated reflex, 4—sustained clonus. In addition, sacral reflexes (bulbocavernosus/clitorocavernosus and anal wink) and plantar reflex are also tested.

Determination of sensory level: This is the most caudal, intact dermatome having a score of "2" for both light touch with a cotton swab and pinprick sensation with a needle. Important dermatomes from C2 to S4–5 are examined on either side. Sensory grading is: 0—total sensory loss, 1—some sensation present, 2—normal sensation. *Dermatome* is the area of skin supplied by a single nerve root. *Important dermatomes are:* C5—deltoid region, C6—thumb, C7—middle finger, C8—little finger, T4—nipple, T8—epigastrium, T10—umbilicus, T12—groin, L3/4—medial aspect of thigh above knee, L5—first web space, S1—lateral border of foot, S2—ischial tuberosity, S3/4—perianal. *Determination of motor level:* Grade 0—complete paralysis, Grade 1—flicker of contraction, Grade 2—movement with gravity eliminated, Grade 3—movement with gravity but not against resistance, Grade 4—against resistance but less than normal power, Grade 5—normal power. The motor level is the lowest muscle group with 3/5 grade of power.

Myotome is a group of muscles innervated by a single nerve root. The important myotomes are as follows:
Upper limb: C5—shoulder abduction, C6—elbow flexion, C7—elbow extension, C8—finger flexion T1—finger abduction. *Lower limb*: L2—hip flexion, L3—knee extension, L4—ankle dorsiflexion, L5—great toe extension, S1—ankle plantar flexion.

The neurological level is the most caudal level of the spinal cord with intact sensation (at least grade 2) and muscle power of at least 3/5. Absent reflexes represent lower motor neuron (LMN) paralysis whereas exaggerated reflexes represent upper motor neuron (UMN) paralysis. The appearance of spinal reflexes indicates recovery from spinal shock. The most sensitive predictor for recovery is the completeness or incompleteness of injury.

MANAGEMENT

Nonoperative Management of Spinal Cord Injury

Traditionally, all SCIs were treated nonoperatively with a spinal brace for a period of 6–8 weeks combined with bed rest. With advances in radiology and surgical techniques, many patients are being operated.

Operative Intervention

Indication, Principle, and Timing of Surgery

The indications of operative intervention are: (1) neurological deficit and (2) unstable spine. The goals of surgery are decompression to relieve pressure, ensuring an adequately sized canal, and fixing the vertebral column after aligning the bones. Surgery entails removal of the fragments in the canal, thereby relieving cord pressure. Fixation is done with rods,

plates, and screws to one to two levels above and below the fractured.

Timing of decompression: Many studies have showed improvement in neurology with grade improvement by 2 or more over 3–6 months after early, i.e., <24 hours, decompression. The results have been better mainly in cervical spine injury.

Spinal instability: White and Panjabi described three subsystems for stability: (1) Passive—spinal column, (2) active—spinal muscles and tendons, (3) control—neural feedback.

ADJUNCT THERAPY

Pressure Sores

Patients are prone to develop bedsores due to immobility. Vulnerable areas are the sacrum, trochanteric regions, heels, elbows, and occiput. Measures to prevent bedsores are: (1) Early removal of spine board, (2) Water bed or alpha bed, (3) Change of position after 2 hours, (4) Smoothening the sheets, (5) Lotions for the back, and (6) Improvement of nutrition. Early aggressive treatment is needed to prevent fatal sepsis. Once pressure sores develop, debridement is followed by vacuum-assisted closure (VAC) therapy and flap cover.

Prophylaxis against Deep Venous Thrombosis

Pneumatic compression stockings should be used early. When there is no intracranial, abdominal, or pelvic injury where hemorrhage is likely, low-molecular-weight heparin should be used. Calf pumps can also be used.

Chest Physiotherapy

Patients are prone to retaining tracheobronchial secretions and developing atelectasis and other pulmonary complications. Steam inhalation, saline nebulization, deep breathing maneuvers, chest physiotherapy, and incentive spirometry are preventive.

Urinary Tract Infection

With immobilization and bladder denervation, patients develop retention leading to urinary infection. Foley's catheterization is initially followed by condom drainage or clean self-intermittent catheterization (CSIC) in the long term.

Neurorehabilitation

This is done to strengthen the muscles and improve range of *movement. Functional electrical stimulation and epidural spinal cord stimulation* are done to reduce pain and improve muscle power and bladder function. *Exoskeletons* which are external motorized orthoses improve activity.

EMERGING THERAPIES

Riluzole, a sodium channel antagonist; *minocycline,* a tetracycline group antibiotic; *granulocyte colony-stimulating factor* (G-CSF); *systemic hypothermia*; *stem cell therapy*; *biodegradable polymer scaffolds and hydrogels*; and cethrin inhibitor (Rho) have shown promise to reduce damage and promote axonal growth.

SUMMARY

Adequate safety measures will reduce spine trauma. Cervical collar and spine board are mandatory. The spine board should be removed as early as possible. The cervical collar is removed after clinical examination and radiology. The patient should be carefully logrolled while shifting. Initial management is always airway, breathing, circulation, disability (ABCD). Treatment of other life-threatening injuries takes precedence over the spine. Hemorrhage should always be ruled out in every case of hypotension. Maintain blood pressure and oxygenation. Neurological level of injury helps in severity and prognosis. CT scan is the investigation of choice. MRI is not done often but it is referred especially for cord compression and neurodeficiencies. An unstable spine injury should be operated early ideally within 24 hours. Newer therapies for spinal regeneration are showing promise.

226
CHAPTER

Cardiothoracic Trauma

Pushkin Roy, Devendra Richhariya

INTRODUCTION

Direct thoracic trauma leads to one fourth of all deaths from trauma. Usually, it is caused by motor vehicle crash (MVC) leading to immediate death. This includes myocardial wall rupture and thoracic aorta rupture. Myriad causes of early deaths, 30 minutes to 3 hours from thoracic trauma, are preventable. These include tension pneumothorax, cardiac tamponade, airway obstruction, and uncontrolled exsanguination. Three fourths of thoracic trauma can be managed expectantly with simple tube thoracotomy and blood. We need an efficient trauma system to do well post emergency department (ED) resuscitation. As computed tomography (CT) scans are getting ubiquitous, missed injuries are becoming uncommon. Disruption of these structures can cause catastrophic consequences since the chest wall is critical for ventilation and oxygenation. As the thorax expands outward, the diaphragm expands down and creates negative pressure. Injuries to this region can disrupt this physiology and with significant consequences. Common cardiothoracic injuries are given in **Table 1**.

CHEST WALL INJURY

Chest wall injury (CWI) is a comprehensive term, including soft-tissue injury, rib fracture, flail chest, and sternal fracture, costochondral separation. Approximately 50% of thoracic trauma have a CWI. It is often not obvious and can be overlooked in a secondary survey. An intact chest wall is essential to normal ventilation for the inspiration and expiration cycles. Those with limited reserves have more difficulty; for example, elderly patients with a preexisting pulmonary disease cannot tolerate even a minor injury. We can miss many CWIs if we do not fully disrobe the patient and observe respiratory rate, adequacy of tidal volumes, respiratory effort, palpation for tenderness, deformity, and crepitus.

RIB FRACTURE

Most injuries are simple rib fractures. The susceptibility of rib fractures increases with age. More than the rib fractures, their potential complications need management, i.e., pneumothorax, hemothorax, pulmonary contusion, post-traumatic pneumonia, and liver/spleen injury. In children, rib fractures are correlated with an underlying pulmonary injury. Ribs break at the point of impact or the weakest area, which is commonly the posterior angle/posterolateral area. Usually, 4th to 9th ribs break, 1st to 3rd are protected, and 9th to 12th are mobile and can penetrate intra-abdominally. Suspect spleen and liver injuries in lower rib fractures. Suspect intrathoracic injuries for 1st to 3rd ribs; if more than two ribs fracture, there is a risk for internal injuries.

Clinical Features

Tenderness, bony crepitus, ecchymosis, and muscle spasm are present. The barrel compression test is done to assess pain at the fracture site. Clinical impression and physical findings are not specific to rib fractures. Chest X-ray (CXR) often misses rib fractures but it can find the intrathoracic injuries. Rib-specific views should be ordered in general: Rib series, expiratory, oblique, and cone-down views. The only reason to get an X-ray

TABLE 1: Common cardiothoracic injuries.

Structures involved	***Injuries***		
Airway	Tracheobronchial injury	Traumatic asphyxia	
Lung	Pulmonary contusion	Pneumothorax, hemothorax	Bronchopleural injury
Cardiac	Tamponade	Commotio cordis	Myocardial contusion
Vascular	Intercostal/great vessel disruption	Blunt aortic dissection	
Gastrointestinal	Esophageal perforation	Esophageal disruption	
Chest wall	Rib fracture	Flail chest	

in addition to clinical suspicion of rib fractures is to look into intrathoracic pathology 50% of isolated single rib fractures are missed. CT scans are much more sensitive. Order a CT scan if the following are present: dangerous mechanism of injury, physical examination findings of multiple rib fractures, elderly patient, lower rib fractures, and hemodynamic or respiratory compromise.

Management

Rib fractures can be managed by controlling the pain, and maintaining pulmonary function, and continuing with daily activities and deep breathing. Chest wall binders should be avoided because they promote hypoventilation and atelectasis. This has never been supported with research or science though. Generally, people with more than three rib fractures may need hospitalization for pulmonary therapy and analgesia. Especially in elderly, intercostal nerve block should be given by using 1% lidocain and 0.25% bupivacaine along the inferior rib margin several centimeter posterior to site of fracture, which block one rib above and one rib below. Most rib fractures heal within 3–6 weeks. Analgesia is usually needed for 1–2 weeks.

Complications

Pneumothorax, hemothorax, pulmonary contusion, post-traumatic pneumonia, liver/spleen injury, post-traumatic neuroma, costochondral separation, and separated rib fractures can lead to delayed hemorrhage due to torn intercostal artery that can rebleed.

FLAIL CHEST

Flail chest can be a life-threatening injury due to high energy injury. It is usually associated with lung parenchymal injury. Flail chest is defined as three or more ribs fractured at two points leading to paradoxical chest wall motion. It can also occur with a vertical sternal fracture/costochondral injury. This is one of the most serious chest wall injuries with 8–36% mortality rate, especially in those with bilateral flail segments. The lung contusion/parenchymal injury leads to altered ventilation/oxygenation. The pain from the fractures leads to hypoventilation, hypoxia, atelectasis, etc. Physical examination requires a thorough examination of the entire chest for asymmetrical movement. Specific visual inspection can be guided by pain/crepitus. Endotracheal intubation will mask the paradoxical movement. The exact rib fracture and pulmonary contusion will be found best on CT scan which can be easily missed on chest X-ray.

Management

There is no ideal prehospital management. It is important to watch and deal with pain and hemopneumothorax expeditiously. These should be related before considering intubation. Continuous positive airway pressure (CPAP)/noninvasive oxygenation strategies should be attempted first. Consider continuous cardiac monitoring and also serial cardiac enzyme estimation given the risk for cardiac injury and dysrhythmias. Intubation is done only for ventilatory failure despite chest physiotherapy, oxygen/noninvasive positive-pressure ventilation (NIPPV), analgesia, high-nerve blocks, and epidural analgesia. People treated with these have much fewer complications. Consider open reduction and fixation of the rib fractures for patients in whom multiple ribs are involved, leading to decreased respiratory function, requirement of ventilation, and incessant pain (**Figs. 1A** to **F**). There evidence to support that they have improved recovery, better cosmetics, and improved function in those getting surgery. Long-term complications are chronic pain, dyspnea, and chest wall deformities.

COSTOCHONDRAL SEPARATION

Due to blunt trauma to the chest, i.e., an injury to the cartilage, patients have a snapping sensation with deep inspiration. Poorly detected on X-ray, it takes many weeks to heal fully.

NONPENETRATING BALLISTIC INJURY

The kinetic energy is so high during trauma that in spite of an intact chest wall cavity, the energy is enough to damage the liver, lung, kidney, heart, and spinal cord. *Situations*: Trauma caused by people wearing bullet-resistant/bulletproof vests, due to rubber bullets, and due to bean bags. Clinical findings are pain, areas of bruising, and tenderness. Key features not to be missed are crepitus, subcutaneous air, retained foreign bodies, and bony step-offs. Basic radiography should be performed to exclude foreign bodies and associated pneumothorax/hemothorax. CT scan should be considered. Most of the patients should be admitted for overnight observation and serial examination. Consider serial abdominal examinations or CT of abdomen if available. Do not underestimate the risk and extent of injuries in the absence of penetration.

STERNAL FRACTURE

Sternal fracture occurs due to anterior blunt chest wall trauma, more likely in restrained passengers. It is usually due to the diagonal strap running across the sternum. A sternal fracture can mean that less energy was dissipated to the internal organs. This may be associated in 10% of cases with rib and lung contusions.

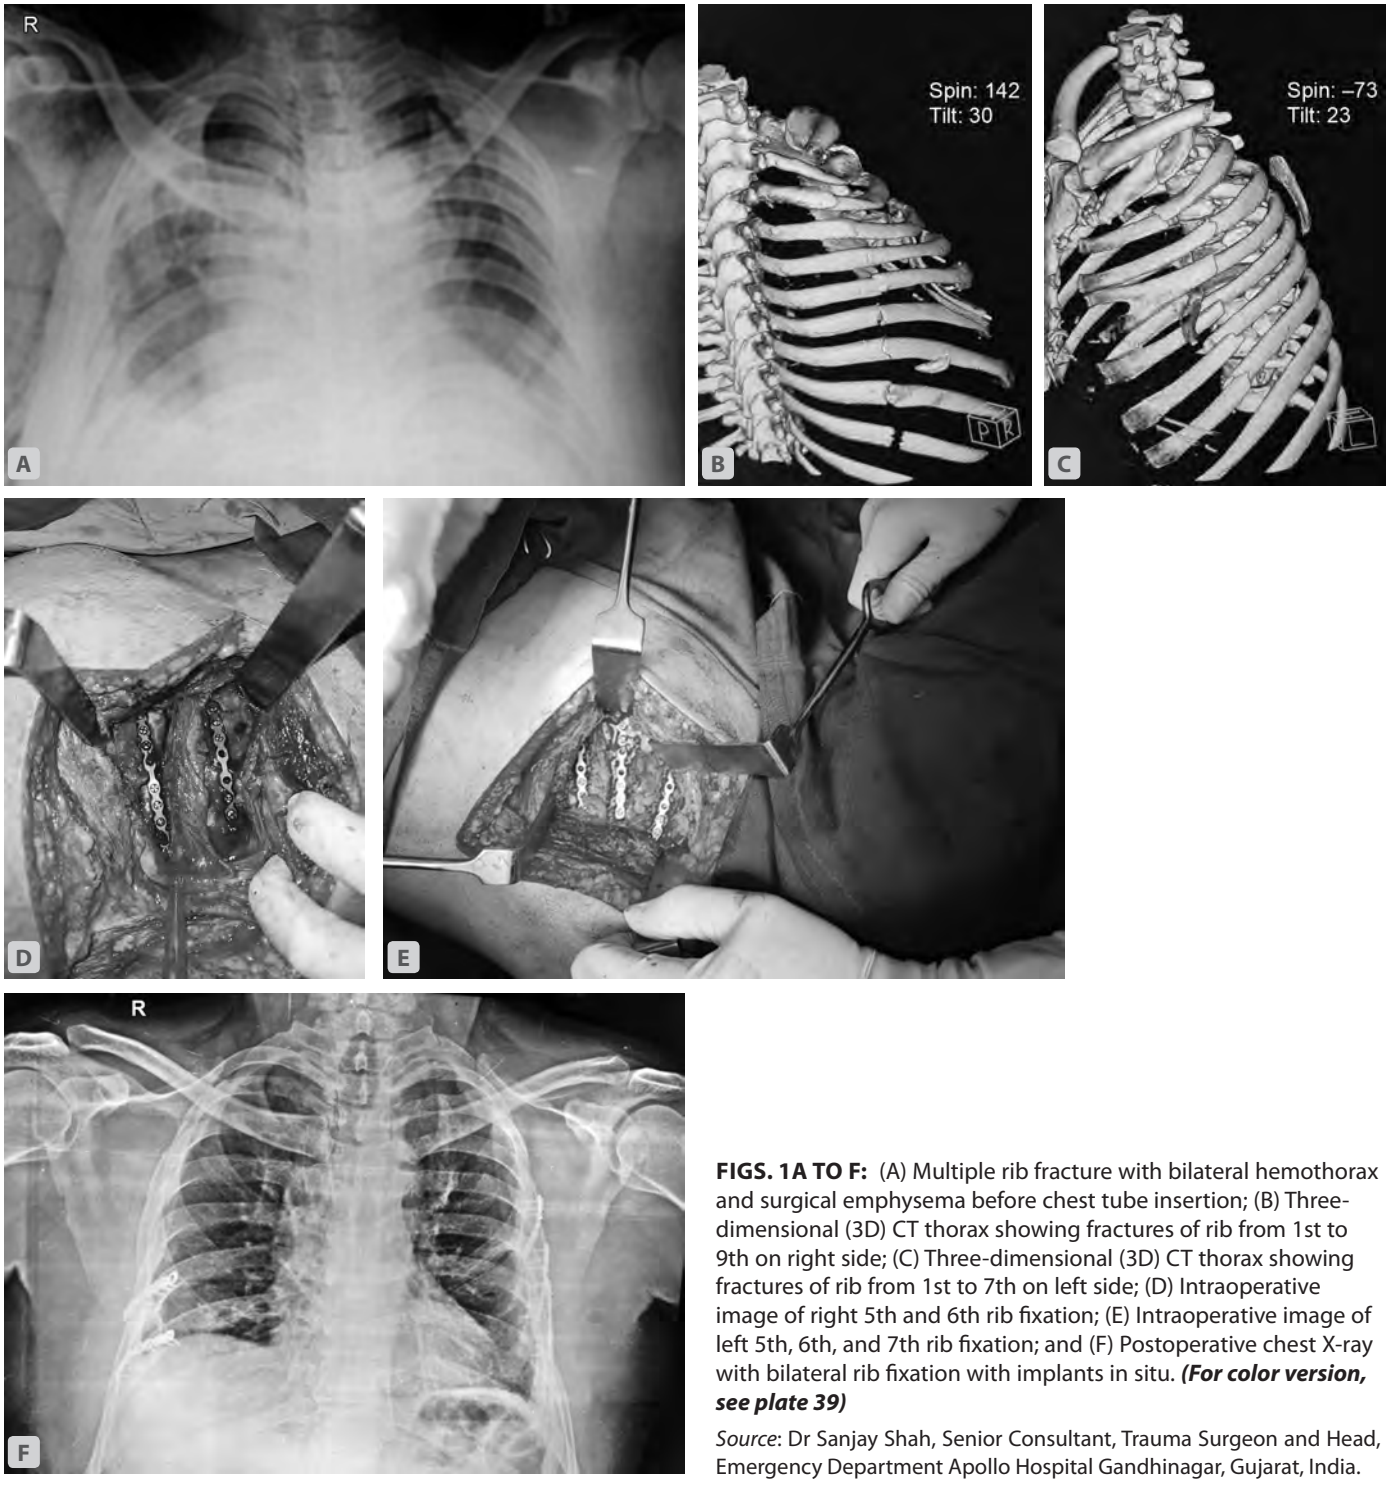
Nondisplaced sternal fractures: Benign, <1% mortality, and low intrathoracic morbidity, although mediastinal injuries should be considered. Cardiac complications are rare, 1–6%. There is no association with aortic rupture. The main complications are mediastinal hematomas, which can lead to blood loss. Clinical features are anterior chest pain with point tenderness, swelling, ecchymosis, and deformity.

Diagnosis: Anyone with a suspected sternal fracture should get a CT scan. CT chest is preferred investigation over ultrasound chest and X-ray.

Everyone should get an electrocardiogram (ECG) done. Sternal fracture can be managed by analgesia. Discharge home if there are no other injuries. Rarely surgery is required, only in cases of displaced sternal fracture or if lung parenchymal injury is present.

SUBCUTANEOUS EMPHYSEMA

In the presence of thoracic trauma, free air in the subcutaneous tissue represents an injury to air-containing structures: Sub-



FIGS. 1A TO F: (A) Multiple rib fracture with bilateral hemothorax and surgical emphysema before chest tube insertion; (B) Three-dimensional (3D) CT thorax showing fractures of rib from 1st to 9th on right side; (C) Three-dimensional (3D) CT thorax showing fractures of rib from 1st to 7th on left side; (D) Intraoperative image of right 5th and 6th rib fixation; (E) Intraoperative image of left 5th, 6th, and 7th rib fixation; and (F) Postoperative chest X-ray with bilateral rib fixation with implants in situ. ***(For color version, see plate 39)***

Source: Dr Sanjay Shah, Senior Consultant, Trauma Surgeon and Head, Emergency Department Apollo Hospital Gandhinagar, Gujarat, India.

cutaneous air in the supraclavicular and anterior neck areas is due to pneumomediastinum. Subcutaneous air in the chest wall is due to an intrapleural injury or penetrating trauma.

Extrapleural injury: From the tracheobronchial tree air leaks in to the mediastinum and neck but it rarely leads to tension pneumomediastinum. It rarely leads to tension pneumomediastinum. It may have Hamman's crunch on heart auscultation. It is worsened by positive pressure ventilation.

Intrapleural injury: It occurs due to a break in the visceral and parietal pleura. Air then tracks into the subcutaneous tissue. Other etiologies are Boerhaave's syndrome—air in the neck and supraclavicular area. Blunt or penetrating chest trauma occurs with or without an intrapleural injury.

Management

Tension pneumothorax or tension pneumomediastinum, all need drainage urgently, with chest tube or pericardiocentesis. Smaller accumulations are treated on the basis of an underlying injury: Bronchial wall rupture, pneumothorax, and esophageal injury. Patients with isolated subcutaneous air should receive high-flow oxygen to help absorb the nitrogen-rich subcutaneous air which causes discomfort.

PULMONARY CONTUSION

The most common significant injury in blunt chest trauma in 30–70% of cases is pulmonary contusion.

High-risk populations for pulmonary contusion are: MVCs, pedestrian struck by motor vehicle, shock-wave-induced injury from a bomb blast in air or water, and ballistic or missile injuries. These are very common in children. *Pulmonary contusion is defined as*: Bruise to lung parenchyma tissue leading to alveolar hemorrhage and edema. It must be suspected clinically; the onset may be insidious and quickly become life-threatening. There are no clear signs to suggest pulmonary contusion. It may commonly present with rib fractures and flail segments. But the most severe contusions may present as dyspnea, absent breath sounds, rales, hypotension, hypoxia, hemoptysis, tachycardia, and cyanosis. An emergency physician must be careful not to miss the diagnosis. Clinical suspicion may arise in the presence of other injuries such as rib fracture, subcutaneous air, and pneumonitis. The X-ray may show frank consolidation or patchy, irregular, alveolar infiltrates.

Acute respiratory distress syndrome (ARDS) versus pulmonary contusion: Pulmonary contusion appears in the first minutes to 6 hours and lasts for 24–48 hours. ARDS is diffuse and bilateral, has a slow onset, and comes on after 24–72 hours. X-ray is much more effective at diagnosing clinically significant pulmonary contusions. CT scan of the chest is more sensitive (2×) than X-ray, especially in the acute phase, and will find other potential injuries/issues. However, many of the contusions may be occult and not as clinically important. Arterial blood gas (ABG) is probably the best means of assessing progression in the contusion (increasing A-a gradient). If the pulmonary contusion can only be seen on CT, it is probably not clinically significant enough to change outcomes (handle it like any other blunt trauma to the chest). But if it is seen on CXR and CT, these carry a high morbidity.

Management

Avoid over administration of intravenous (IV) fluids and follow good pulmonary toileting, good pain control, no colloids, no prophylactic antibiotics. Avoid intubation and mechanical ventilation, especially in the context of flail chest (shown to increase morbidity). If intubation is needed, use a double-lumen tube so that ventilation strategies can differ between the lungs; lung protective strategies. Consider using CPAP and bilevel positive airway pressure (BiPAP). Also consider extracorporeal membrane oxygenation (ECMO) in severe cases.

PULMONARY LACERATION

It is not commonly seen. But it can be found due to penetrating trauma, rib segment tearing the lung, or a torn pulmonary adhesion. It can lead to persistent bleeding and hemopneumothorax. Management consists of oxygen therapy, observation, and if required thoracostomy or operative repair.

PNEUMOTHORAX

Pneumothorax occurs due to an injury in the parietal pleura. It leads to paradoxical lung movement, collapse with inspiration due to negative intrapleural pressure, and expansion with expiration. Different types of pneumothoraces are as follows:

Simple pneumothorax has no communication with the atmosphere and no mediastinal or diaphragm shift. It can be small, moderate—15–60% of lung collapsed, and large. It is often due to rib fracture/penetrating trauma tearing the parietal pleura. It may be due to blunt chest trauma with a full breath and closed glottis leading to an alveoli rupture.

Communicating pneumothorax is due to an open connection with the outside atmosphere, creating a sucking chest wound. It is common in shotgun trauma and leads to paradoxical chest wall and lung movement.

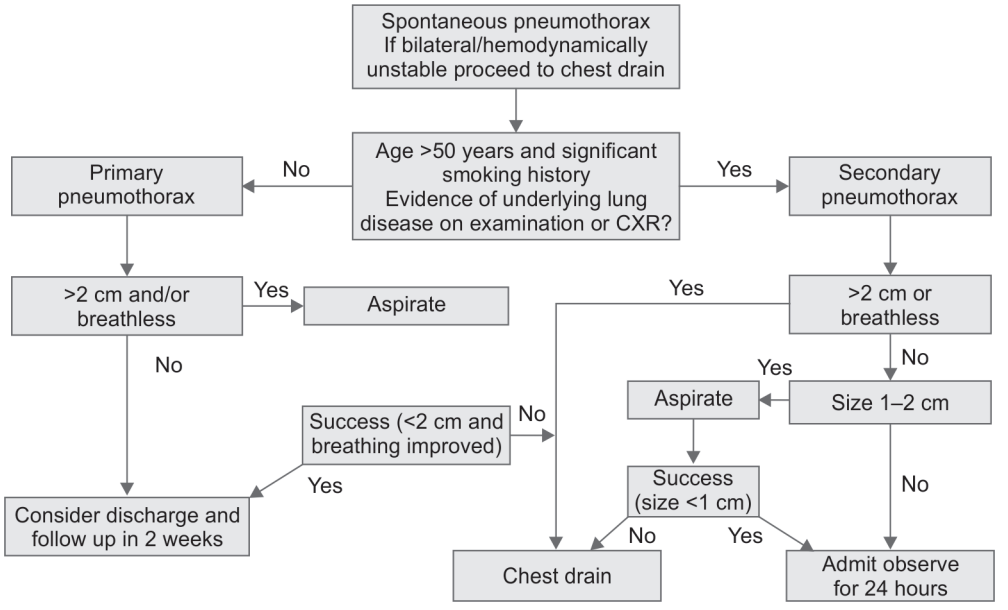
Tension pneumothorax is a life-threatening chest wound leading to a one-way valve, drawing more and more air into the chest without an escape, leading to lung collapse and contralateral compression of the lung, great vessels, and venocaval structures. This leads to shock, hypoxia, decreased cardiac output, and death.

Clinical features of pneumothorax are dyspnea, chest pain, subcutaneous air, and wide spectrum based on severity, from cyanosis to no symptoms. This may have tachypnea, tachycardia, altered mental status, hypotension, tracheal deviation away from the side of the injury, unilateral absence of breath sounds, and neck vein distension. In ventilated patients, early reliable signs are decreasing saturation and blood pressure (BP) and tachycardia. Look for raised ventilation pressure (>40 mm Hg) and ensure that the ventilator pressure alarm settings are set appropriately. The triad of tension pneumothorax is jugular venous distension, absent breath sounds (hyperresonance), and tachycardia; hypoxia occurs first and hypotension is a preterminal state.

Diagnosis: This can be very accurately differentiated on extended focused assessment with sonography in trauma (eFAST) ultrasound during the primary survey. It is found to be more accurate than X-ray. Chest X-ray should be done in upright position and on maximum inspiration. This may miss 30% of pneumothoraces initially; if still suspected, do another film on expiration. CT scan is much more sensitive and may detect "occult" pneumothorax that was not found on X-ray. Tension pneumothorax is a clinical diagnosis and X-ray rarely should delay treatment, although findings may be subtle at times. The approach to pneumothorax is shown in **Flowchart 1**.

Management

Management depends on the size and clinical condition of the patient. In case of blunt trauma, if the initial CXR is negative, then a repeat should be done at 6 hours. If no pneumothorax is found on the CT scan of the chest, the patient may be discharged after appropriate treatment. If CXR is performed and is negative, then repeat CXR should be done at 3 hours. Simple pneumothorax size and symptoms usually guide treatment: If <15%, whether blunt or penetrating or spontaneous or traumatic, usual observation is adequate. If >15% and/or symptomatic: Tube thoracostomy is the best option. It is safer and less scarring than going anteriorly in the second intercostal space in the midclavicular line (**Box 1**). Size depends on age. Ensure that it is placed apical-posteriorly and that radiographic lines are inserted fully into the chest. If there are apical pneumothoraces, due to penetrating trauma, stable patients with <25% involvement may be followed conservatively. In the setting of multisystem trauma,



(CXR: chest X-ray)

FLOWCHART 1: Approach to pneumothorax.

conservative observation is rarely safe or indicated, but this is based on clinical judgment.

Communicating pneumothorax: Three-side occlusive dressing is applied that allows air to escape. Tube thoracostomy can be placed in the ED.

Tension pneumothorax: Emergent needle thoracocentesis—it must be decompressed with needle thoracostomy or by at least a 5-cm 14G angiocatheter; common site of insertion is in the 2nd intercostal space at the midclavicular line or the lateral chest 4–5th interspace anterior axillary line. The chest tube must be performed immediately after needle decompression. It is inserted over the top of the fifth rib in the midaxillary line. The most common cause of serious injury as a result of chest drain insertion is incorrect site of placement. Confirm that the drain lies within the chest wall cavity by looking for fogging of the tube and swinging of the chest drain with respiration. Do not clamp the chest drain or apply suction. The underwater seal needs to remain below the insertion site at all times. Gross surgical emphysema with pneumomediastinum and a chest drain that continues to bubble suggests a tracheobronchial injury. Cardiac tamponade can give similar signs clinically and shock with distended veins. A combination of focused assessment with sonography in trauma (FAST) and CXR along with the mechanism of injury can help to differentiate between the two.

Complications

Complications of pneumothorax are bronchopleural fistula, empyema, scarring, pleural leaks, intercostal artery/vein injury, and pneumonitis. There is an increased risk of re-expansion pulmonary edema for pneumothoraces that have been present for >3 days.

HEMOTHORAX

Hemothorax can occur with blunt or penetrating trauma with extrathoracic injury and lead to massive blood loss and altered chest ventilation. It clinically presents as varying degrees of hypovolemic shock, increased tactile fremitus, and decreased breath sounds. A supine film CXR will often miss blood unless there is a large amount that layers posteriorly. It needs at least 200–300 mL of blood to blunt the costophrenic angles. It may see a tension hemothorax (rare). Ultrasound may be used to see a pleural effusion with accuracy. CT scan of the chest is much more accurate.

BOX 1: Indications for tube thoracostomy.

- Traumatic cause of pneumothorax (except asymptomatic, apical pneumothorax)
- Moderate-to-large pneumothorax
- Respiratory symptoms regardless of the size of pneumothorax
- Increasing size of pneumothorax after removal of the initial conservative therapy
- Recurrence of pneumothorax after removal of the initial chest tube
- Patient requires ventilator support
- Patient requires general anesthesia
- Associated hemothorax
- Bilateral pneumothorax regardless of size
- Tension pneumothorax

Management

Priorities are to restore blood volume, control airway control, and drain hemothorax using a large tube attached to a Pleur-evac. Most worrisome is continued loss of blood >200 mL/h for 3 consecutive hours. The CT scan is important, because the presence of a hemothorax often leads to tube drainage (when it is symptomatic or moderate in size). Small hemothoraces may be observed, but no study has been done to exactly describe which sizes of hemothorax need drainage. Massive

hemothoraces need operative thoracotomy or video-assisted thoracoscopic surgery (VATS).

Complications

It causes delayed hemothorax, leading to empyema and fibrothorax. Errors in tube placement lead to lung parenchymal injury or persistent air.

TRACHEOBRONCHIAL INJURIES

Clinical Features

Tracheobronchial injury most commonly presents as subcutaneous emphysema due to mediastinal air tracking into the neck. An airway injury is suspected with persistent, large air leak with respiratory collapse. Other red flag signs are stridor, hoarse voice, and difficulty swallowing. During the initial resuscitation, tracheobronchial injuries may remain unrecognized in the emergency room; although rare, they are life threatening in the first hour. Predisposing factors for tracheobronchial tree injuries are force to the chest against a closed glottis, rapid deceleration, or direct disruption from a crush injury. Blood, vomit, or foreign bodies can directly obstruct the airways and present with stridor, respiratory distress or failure, or hypoxia and cyanosis but usually without subcutaneous emphysema.

Diagnosis

Chest radiographs may demonstrate pneumothoraces and subcutaneous emphysema but will not localize tracheobronchial injuries. A high clinical suspicion is required to initiate the diagnostic process. Most of the tracheobronchial injuries (not all) can be identified by CT imaging and bronchoscopy is often helpful in these cases in diagnosing as well as identifying the location of the tracheobronchial injuries.

Management

Most tracheobronchial injuries are recognized after the stabilization of patients. Endotracheal intubation with bronchoscopy is considered when the tracheal injury is suspected. Tracheostomy or cricothyroidotomy is emergently required which allows tracheobronchial injuries to manage conservatively, but most injuries will require surgical repair.

TRAUMATIC ASPHYXIA

Clinical Features

Traumatic asphyxia is a rare phenomenon. It is seen in high-speed road traffic accidents and improperly restrained passengers or as a complication of crush injuries to the head or torso. With compressive force to the abdomen against the closed glottis, intrathoracic and mediastinal pressure tend to increase. As a result of this right atrial blood is pushed in to the innominate and jugular vein, resulting capillaries break in the cervicofacial region. As early as 2–3 hours after the injury, patients may present with facial and bulbar conjunctival petechiae, oral mucosal petechiae, facial edema, and facial cyanosis. Agitation, loss of consciousness, confusion, seizures, anoxic injury, cerebral edema, or ischemia are less common.

Management

Most cases of traumatic asphyxia carry a good prognosis and resolve spontaneously. Goals of management include adequate oxygenation and adequate cerebral perfusion to promote healing and avoid secondary neurologic injury. Mild symptoms usually reverse in 1–2 days. Patients who survive the initial hours of management prognosis remain favorable.

DIAPHRAGMATIC INJURIES

Clinical Features

Most diaphragmatic injuries occur when the abdomen is forcibly compressed and the diaphragm is stressed by high pressures. The timing of impact in the respiratory cycle plays an important role. In two thirds of cases, the left hemidiaphragm injury is common and mostly in the posterolateral area. Liver and spleen injuries accompany most diaphragmatic injuries. In rare instances, penetrating trauma can directly injure the muscle of the diaphragm. Diaphragmatic injuries may remain asymptomatic in the initial phase and they are usually missed even after examination. Bowel sounds in the chest are indicative of diaphragmatic injury. In severe defects, respiratory distress occurs as the bowel compresses the lung parenchyma which requires emergent surgical repair. Diaphragmatic injuries will present in a delayed fashion if visceral herniation does not occur initially. Vague chest pain, difficulty breathing, vomiting, or bowel obstruction are the delayed presenting features.

Diagnosis

The subtle radiographic findings in these injuries include opacifications in the lung bases, air above the diaphragm, pleural effusions, displacement of the stomach bubble into the thoracic cavity, or a nasogastric tube in the chest. Diaphragmatic injuries can be diagnosed by CT imaging which are usually missed on a radiograph. Radiologic features, an abnormal diaphragmatic line or high-riding diaphragm, and presence of intestinal loops in the chest with or without pleural effusion strongly suggest diaphragmatic injury.

Management

The main goal of ED management is to recognize the injury and support the patient's respiratory function in severe cases. Surgical repair is required in most patients and is highly successful. Pulmonary hypertension and permanent lung parenchymal damage may complicate delayed presentations of diaphragmatic injury.

ESOPHAGEAL INJURIES

Clinical Features

Esophageal injury is rare but can occur with extreme increases in intra-abdominal or gastric pressure from blunt trauma. The esophagus is one of the best-protected structures of the thorax. Blunt thoracic trauma causes esophageal injury in <0.1% of patients. Chest pain or epigastric pain with mediastinal air, fever or sepsis, or pleural effusion should prompt consideration of esophageal disruption.

Diagnosis

Both water-soluble contrast esophagogram and esophagoscopy are required to fully evaluate esophageal injuries. Chest radiographs may increase suspicion of esophageal injury if infiltrates, pleural effusion, or pneumomediastinum is present in patients with clinical symptoms. Fluid accumulation in the mediastinum will cause widening. To detect an esophageal injury, CT scan has increased sensitivity over radiographs. On a CT scan, perforation may appear as focal extraluminal air at the site of esophageal injury.

Management

The main goal of ED management is early recognition. Fluids and broad-spectrum antibiotics may be initiated as an initial therapy. Surgical closure is common in adults, but most children can be managed with supportive care and drainage of any infectious fluid collections. Antibiotics and parenteral nutrition are required to allow the injury to heal. Surgical repair should be performed in patients who fail to improve and with complications.

BLUNT CARDIAC INJURY

Blunt cardiac injury (BCI) is not a straightforward entity. Complications range from asymptomatic ecchymosis to sudden death. There is no widely accepted definition, no gold standard diagnostic test, difficult to quantify, and little consensus on how to establish the diagnosis. Research and understanding about the diseases are limited. Quantification of this disease becomes difficult due to inconsistent nomenclature also. Complications, diagnostic testing, laboratory evidence, or postmortem examination are helpful in identifying the BCI. Due to lack of uniformity and specificity, there is lack of well-validated diagnostic and treatment algorithms for BCI. Mattox et al. proposed to use the term blunt cardiac injury for all cardiac conditions resulting from blunt trauma and avoid using terms such as cardiac concussion and cardiac contusion. BCI-related specific conditions are septal rupture, free wall rupture, coronary artery thrombosis, cardiac failure, minor ECG/enzyme abnormality, or complex arrhythmia. In most cases, BCI is associated with MVC. Blunt thoracic trauma with multisystem involvement carries a high risk of BCI. One study concluded that there is 13% incidence of BCI with significant chest wall trauma (multiple rib or sternal fractures, lung contusion, scapular fracture, hemopneumothorax, major intrathoracic vascular injury, or seat belt sign). These studies provide a rationale of screening for BCI which identifies cases at high risk for the complication that will benefit from intervention.

Mechanisms and Injury Patterns

There are various mechanisms of injury identified for BCI, e.g., direct, indirect, crush injury, bidirectional or compressive, decelerative, blast, concussive, and combined. Because of its proximity to the chest wall right heart is the most common site for BCI although involvement of multiple cardiac chambers is seen in half of the cases.

Cardiac concussion (cardiac contusion): Cardiac concussion is histologically defined by myocardial hemorrhage, edema, and localized necrosis. In clinical practice, the term broadly describes injuries from chest wall tenderness to wall motion abnormalities, decreased contractility, arrhythmia, or conduction abnormalities. Most of these injuries typically subside within 24 hours without intervention and do not manifest long-term effects. Prompt further evaluation and management are required if associated clinical features such as hypotension, pulmonary edema, malignant arrhythmia, or conduction disturbances are present and represent significant contusion.

Commotio cordis: This is a condition of sudden cardiac death from BCI without any evidence of morphologic injury or preexisting disease. This condition is differentiated from contusio cordis, which does have evidence of an underlying morphologic injury and requires autopsy for differentiation. Alcohol use, drug use, and preexisting cardiovascular disease increase the risk of commotio cordis. Commotio cordis is the second most common cause of sudden cardiac death in young athletes. High-velocity impact to the chest, occurring during ventricular repolarization, is the most suitable pathophysiologic explanation for this condition. Rapid recognition of dysrhythmia and prompt, high-quality cardiopulmonary resuscitation may result in improved outcomes for these patients.

Cardiac rupture: It is possible to have cardiac wall rupture by blunt injury, in most cases fatal, and patients typically succumb rapidly to exsanguination, cardiac tamponade, or other concomitant injuries. Survival in patients with cardiac rupture with BCI is notably rare, but not nonexistent. Overall, ventricular rupture occurs more commonly than atrial rupture, but right atrial rupture is more common than left atrial rupture. The presence of a murmur, thrill, arrhythmia, or conduction disturbance suggests this injury, and the severity of the signs typically correlate with the size of the injury. Cardiogenic shock is the common presentation of severe injury.

Valvular injury: BCI-associated valvular injuries are typically acutely severe, hemodynamically consequential, and clinically manifests with cardiopulmonary sequelae, but minor valvular abnormalities detected during screening for BCI likely represent preexisting valvular disease amenable to repair if diagnosed. The morbidity and mortality of BCI-associated valvular injury depend on the location and severity of the injury of the affected valve. Aortic valve injury is considered to be most common and manifests as cardiovascular instability or cardiogenic shock. It may result from a sudden increase in intrathoracic pressure against a closed valve along with retrograde aortic pressure wave from a concomitant increase in intra-abdominal pressure. Acute mitral valve injury typically manifests as pulmonary edema and hypotension. These injuries are treated by afterload reduction and supportive care till definitive surgical repair. Tricuspid injury may present more subacutely with long-term sequelae of right ventricular dysfunction manifesting over months to years. In addition, injury to the papillary muscle or chordae tendineae injury is associated with higher morbidity and mortality.

Coronary artery injury: There is not enough evidence that suggests that coronary artery thrombosis occurs as a direct result of BCI. Most of the coronary artery injuries may progress to laceration, dissection, aneurysm formation, and/or aneurysm rupture.

Pericardial injury: The pericardium rupture of injury is not common in the setting of BCI. Pericardial injury may clinically present as pericarditis or pericardial effusion and tamponade.

Dysrhythmias: BCI most commonly manifests as sinus tachycardia, ventricular or atrial premature contractions, and atrial fibrillation. Most of the dysrhythmias may be associated with benign features, due to catecholamine release, alcohol and drug use, or electrolyte abnormalities. In many cases, they may occur as a delayed presentation of injury. In severe trauma heart block, ventricular tachycardia, or fibrillation is associated with electrolyte disturbance, acidemia, and/or hypovolemia/hypotension.

Diagnosis

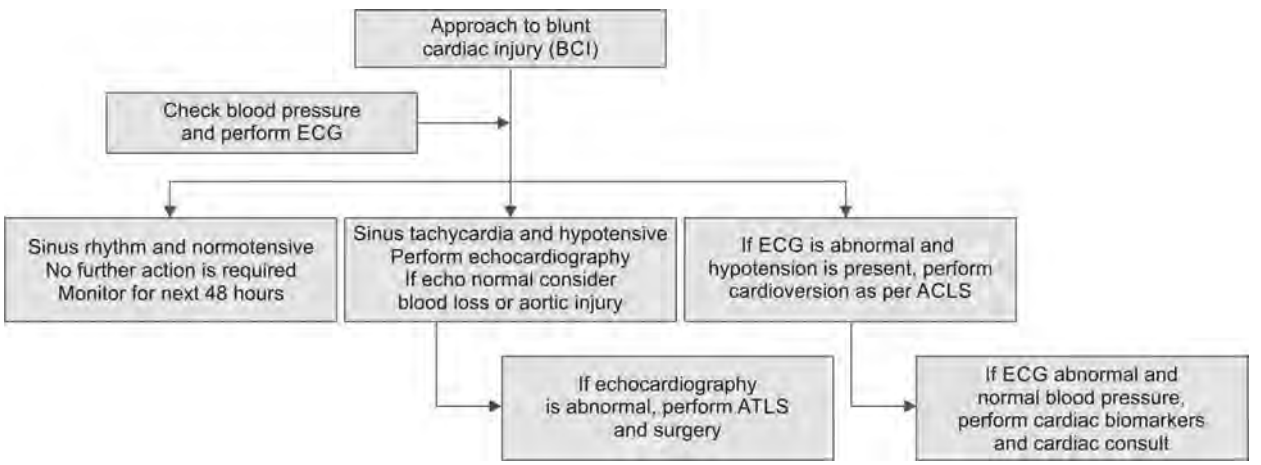
Blunt cardiac injury is a heterogeneous category of multiple specific injuries and thus a difficult condition to diagnose. The history and physical examination mostly remain nonspecific. Patients may complain of chest pain or shortness of breath; in some cases, this even includes typical angina pain, and patients may progress to myocardial infarction via an unknown mechanism. However, in polytrauma conditions, the signs and symptoms of clinically significant BCI may be masked due to other injuries. The physical examination in BCI often remains nonspecific, but findings suggestive of the high-risk mechanism of injury are ecchymosis, chest tenderness, flail chest, and crepitus. The presence of rib or sternal fractures also provides a clue for the emergency physician to proceed with the evaluation of BCI. On physical examination, findings such as friction rubs, distant heart sounds, and new murmurs are much more indicative of BCI, but difficult to appreciate ED setting, especially during polytrauma management. The high index of suspicion for BCI should be considered if patients present with dyspnea, distended jugular veins, chest wall ecchymosis, flail chest, sternal fracture, rib fracture, pneumothorax, hemothorax, great vessel injury, or hemodynamic instability which is not explained otherwise. Once the history and physical examination are completed, ECG should be performed on all patients with direct blunt chest injuries and also in patients without known blunt chest injuries. Electrocardiographic abnormalities may include sinus tachycardia, arrhythmias, and ST-segment changes. Most guidelines and supporting literature have suggested that despite a normal ECG, echocardiography should be performed as some time ECG abnormalities typically manifest within 48 hours of injury. To exclude the myocardial injury negative troponin I assay is also considered with an ECG. Creatine kinase-myocardial band (CK-MB) is neither sensitive nor specific for the detection of BCI and is no longer recommended in the diagnostic evaluation.

The combination of ECG and troponin I is adequate to exclude clinically significant injury. Echocardiography should further characterize injuries if present when these screening tests are abnormal. This test includes quantifying the degree of left ventricular dysfunction resulting from contused or concussed myocardium (appearing as an area of thickened myocardium during end-diastole) and identifying associated valvular disorders. Although the transesophageal approach is superior for the evaluation of a valvular disorder in BCI, it is more time consuming and resource intensive. With improvement in ultrasonography technology, the transesophageal approach may not need to be routinely performed. Both modalities can detect pericardial effusion caused by traumatic cardiac rupture.

Other modalities, such as CT, MRI, and magnetic resonance coronary angiography, have significant limitations in the evaluation of BCI, and may be considered only on a case-by-case basis in consultation with a trauma surgeon and/or a radiologist. In the evaluation of BCI, nuclear scintigraphy is not useful.

Treatment

All patients with abnormal ECG or positive troponin level should be admitted for observation (**Flowchart 2**). Patients with dysrhythmias and hypokinesia due to myocardial contusion should be under cardiac monitoring for at least 48 hours. Patients with features of heart failure or cardiogenic shock should be treated with inotropic agents and/or mechanical support. A standard approach should be adopted to manage the arrhythmias and for the use of antiarrhythmics. Correction of electrolyte imbalance, hypoxia, and acidosis; avoiding proarrhythmic medications; and use of defibrillation if necessary are important. Sinus tachycardia remains the most common dysrhythmia which can be managed by correcting the underlying cause, e.g., volume resuscitation, analgesia, or transfusion. Atrial fibrillation is the second most common arrhythmia, frequently caused by alcohol or drug use, fluid deficit, electrolyte abnormalities, and/or catecholamine surge. Such cases may require temporary pacemaker placement in an ED setting. Although rare, a permanent pacemaker



Approach to blunt cardiac injury (BCI)
Check blood pressure and perform ECG
Sinus rhythm and normotensive
No further action is required
Monitor for next 48 hours
Sinus tachycardia and hypotensive
Perform echocardiography
If echo normal consider blood loss or aortic injury
If ECG is abnormal and hypotension is present, perform cardioversion as per ACLS
If echocardiography is abnormal, perform ATLS and surgery
If ECG abnormal and normal blood pressure, perform cardiac biomarkers and cardiac consult

(ACLS: advanced cardiac life support; ATLS: advanced trauma life support; ECG: electrocardiogram)

FLOWCHART 2: Approach to blunt cardiac injury.

placement is required for persistent complete heart block with clinical symptoms. Patients with BCI who have ST-segment elevations on ECG may represent either traumatic myocardial infarction (from coronary rupture, dissection, or thrombosis) or myocardial contusion although there are no standard guidelines to differentiate infarction from contusion. Operative repair and immediate surgical evaluation are required for structural injuries, including myocardial rupture, pericardial rupture, hemopericardium, and traumatic valvular injuries. Depending on the specific structure injured, various temporary measures need to be performed. Mitral valve injuries with significant regurgitation may require vasodilators to reduce afterload and improve the forward stroke volume and ejection fraction. Mechanical support with an intra-aortic balloon pump may also be beneficial before valve repair or replacement in such cases. Aortic valvular injuries typically require emergent surgery not amenable to stabilizing measures. Depending on the degree of hemodynamic instability and the acuity of decompensation, pericardiocentesis or emergent thoracotomy may be indicated for hemopericardium.

INJURIES OF THE AORTA AND GREAT VESSELS

Clinical Features

High-energy mechanisms with rapid deceleration, such as motor vehicle accidents and falls, most commonly result in such injuries. These injuries are less common with penetrating trauma. Aortic injuries frequently occur at the aortic isthmus. Due to high energy mechanism and rapid declaration ascending aorta gets twisted. As a result of shearing force pseudoaneurysms or focal aortic dissection can develop which may be evident as widening of aorta and blurring of mediastinal contour.

Diagnosis

Widening of the mediastinum, loss of a defined aortic knob, presence of pleural effusion, esophageal or mainstem bronchus deviation, apical cap, or first or second rib fractures are the suggestive features on chest radiography, but CT angiography is the diagnostic modality of choice.

Management

Surgical management provides definitive treatment. But a supportive measure is important in the ED which includes pain control and beta-blocker therapy to control the heart rate and BP. The injuries are often fatal. Early recognition by an emergency physician and definitive therapy reduces mortality.

CRITICAL DECISIONS IN THORACIC TRAUMA MANAGEMENT

Any injured patient should be assessed in a systematic fashion. After blunt and penetrating trauma, thorax injuries are common in both situations; therefore, all patients who present to the ED) after trauma should be screened for thoracic injury according to the advanced trauma life support (ATLS) protocol. Because chest injury can impact each of the ABCs (airway, breathing, and circulation), a rapid evaluation of the chest is performed early in the evaluation of the injured patient to look for any life-threatening injuries. Nonlife-threatening injuries to the thorax are detected as part of the detailed secondary survey.

IMAGING TO DIAGNOSE OR EXCLUDE THORACIC INJURY

Once immediately life-threatening thoracic injuries have been excluded or managed, a secondary survey should be performed. The three most commonly used investigations to screen for thoracic injury are the portable, often supine, anteroposterior (AP) CXR; point-of-care ultrasound (POCUS), including eFAST; and CT scan with arterial-phase IV contrast. As with most decision-making in trauma, the selection of imaging investigations in the workup of thoracic trauma depends on the clinical stability of the patient. It is important to emphasize that unstable patients should not go for the CT scan.

Chest radiograph: The CXR is considered the standard initial imaging investigation for all stable or unstable trauma patients. Without moving the patient from a resuscitation trolley, a single-view AP portable CXR is often taken as fast and inexpensive with a low radiation burden and screens the entire thorax for injury. The CXR gives an overview of the lungs as well as mediastinum, aorta, diaphragm, and bony structures, including ribs, thoracic vertebrae, clavicles, sternum, and scapulae. A CT scan should be performed in stable patients with an abnormal CXR.

Point-of-care ultrasound or standard chest radiograph: In trauma, POCUS is referred to as FAST. FAST is appropriate for both stable and unstable patients. A rapid and radiation-free imaging can be obtained in the resuscitation area without transferring the patient anywhere. There are four conventional views in FAST. One of these, the subxiphoid pericardial view, plays an important role in the workup of thoracic trauma, as it assesses the heart for cardiac motion and tamponade. More recently, the eFAST has entered into clinical use with the addition of thoracic views to assess for hemothorax and pneumothorax. The subxiphoid pericardial view has a sensitivity that approaches 100% and a specificity of 97% at detecting penetrating cardiac injuries. Pneumothorax is detected if lung sliding (the normal movement of the visceral on parietal pleural during breathing) and "comet tail" artifacts (hyperechoic signals that result from normal pleural apposition) are absent, or a lung point (the junctional interface between normal and partially collapsed lungs) is observed.

When compared with the gold standard of CT scan, eFAST has a sensitivity of 86–100% and specificity of 97–100% in pneumothorax detection. This diagnostic yield makes eFAST superior to CXR in the investigation of pneumothorax because CXR has a sensitivity of 27–83% and a specificity of 99–100%. eFAST thus detects pneumothoraces that would be occult on CXR, although these injuries generally do not require chest tube placement unless the patient is symptomatic. Although for the assessment of pneumothorax, eFAST is an excellent tool, it does not provide any assessment of the bony elements of the thorax, the mediastinum (apart from the evaluation for pericardial effusion), or the diaphragm, all of which are assessed on CXR. Ultrasound is a user-dependent test and the validity of results depends on the experience of the clinician, which is not so true with CXR. Therefore, eFAST and CXR are complementary to each other rather than competing diagnostic tests.

Cross-sectional imaging: CT scan of the thorax—The CT scan of the chest is the gold standard imaging modality in thoracic trauma for stable patients, with a sensitivity of 75–85% and a specificity of 99–100%. A CT scan has few limitations in spite of its excellent diagnostic capability. It is costly, involved radiation exposure and, most importantly, necessitates the transport of the patient out of the resuscitation area at a critical time of management. Therefore, it is important to carefully select patients who will derive benefit from this diagnostic intervention.

DISPOSITION FROM THE EMERGENCY DEPARTMENT

Most thoracic injuries such as rib fractures, flail chest, and pulmonary contusions can be managed nonoperatively in the intensive care unit. Flail chest is considered when at least two consecutive ribs are fractured in two or more places and can produce significant contusion to the underlying lung parenchyma as the segment of ribs moves paradoxically against the remainder of the chest wall on inspiration and expiration. The resultant pulmonary contusion can cause respiratory decompensation. The cornerstones of flail chest management include aggressive pain control, alveolar recruitment, and careful use of IV fluids in the first few days after injury. Surgical options for flail chest (open reduction and internal fixation with rib plating) should be considered.

Blunt cardiac injury is an injury pattern that occurs due to a high-speed road traffic accident or direct blow to the chest that needs special attention and clinically manifests as either mechanical or electrical cardiac dysfunction. Mechanical BCIs, such as papillary muscle injury or septal or cardiac wall rupture, are frequently fatal and most patients die at the scene or en route to the hospital. Electrical BCI is more common, clinically present as arrhythmia, and usually self-limited. Patients with BCI should be admitted for 24 hours of continuous cardiac monitoring and obtain an ECG and three sets of troponins. Patients who have hypotension, an abnormal ECG, or uptrending troponin levels should have echocardiography done.

Endovascular therapies: The role of endovascular therapy in the management of thoracic vascular injuries is becoming popular in which the injured vascular segment is excluded from the circulation. Although most patients with vascular injury or rupture succumb on the scene or en route, patients with traumatic aortic dissections and intimal flaps are able to reach the hospital in a stable condition and are candidates for endovascular repair. The use of endovascular therapies for both penetrating and blunt trauma is becoming popular.

Operating room: Most surgeons now rely primarily on the patient's physiology, i.e., clinical evidence of shock, to guide intervention and on the indications for operative intervention. However, many surgeons still consider traditional school of thoughts for operative intervention with evidence of ongoing bleeding or chest tube output greater than 1 L, regardless of the patient's hemodynamic status although with increased acceptance of nonoperative management and a rise in the use of catheter-based interventions, early involvement of the surgical team is always most prudent.

SUMMARY

Thoracic injury is common following blunt as well as penetrating trauma, and clinically presentation ranges from a relatively benign occult pneumothorax to a fatal cardiac injury. It is important that an emergency physician be familiar with the physical examination of this condition and imaging options (CXR, eFAST, and CT scan of the chest) for further workup of thoracic trauma. The emergency medicine physician should have sound knowledge of decompressing tension pneumothoraces, quickly placing chest tubes, when indicated. Swift management of life-threatening thoracic injuries and appropriate workup of others will allow the ED physician to successfully manage patients in the ED. Every trauma patient should undergo a rapid clinical examination and several imaging modalities which include ultrasound, plain radiographs, and CT scan to screen for traumatic injuries to the thorax. It is important to be aware of the indications and pitfalls of each. Many thoracic injuries can be managed nonoperatively. Invasive bedside procedures, such as chest tube placement, are critical skills for all emergency medicine physicians who treat trauma patients. An emergency physician should be familiar with resuscitative thoracotomy, a procedure that is indicated for selected patients following penetrating and blunt trauma.

227
CHAPTER

Abdominal Trauma

Sanjay Shah, Chintan Thanki

INTRODUCTION

Up to 25% of hospitalizations due to trauma involve abdominal and pelvic injuries. In patients having polytrauma, up to 20% of deaths result due to abdominal injuries. In abdominal trauma, the most commonly injured organ overall is the liver, and due to sports injuries it is the spleen. Hemorrhagic shock is the most common cause of death due to abdominal trauma whereas infection is the most common form of morbidity. The most commonly involved organs in penetrating abdominal trauma include the liver, small intestine, and colon.

ETIOLOGY

Road traffic accident is the most common mechanism for abdominal trauma. It is the cause in up to 75% of the cases, followed by blows to the abdomen in approximately 15% and falls in up to 9% of the cases of blunt abdominal trauma, and any such history should raise suspicion for the same. All cases of concomitant head or chest injuries must be ruled out for abdominal trauma. Similarly, any abdominal trauma, especially above the level of umbilicus, must always raise suspicion for associated chest trauma. A pelvis fracture should raise concern for any associated abdominal or retroperitoneal trauma. All patients with unexplained shock in absence of external bleeding must be screened for abdominal trauma.

Penetrating abdominal trauma can be caused by gunshot/firearms injury, stab wounds, and assaults in addition to the aforementioned causes of blunt abdominal trauma. Penetrating abdominal trauma may lead to ureter injuries and blunt abdominopelvic trauma may lead to urinary bladder injuries. Gunshot injuries have a lower incidence but higher overall morbidity than other penetrating abdominal injuries and up to 90% mortality. Up to 10% of children admitted for trauma have an abdominal injury, and road traffic accident is the most common cause, followed by child abuse. **Table 1** summarizes the etiology of blunt and penetrating abdominal trauma.

PATHOPHYSIOLOGY

Victims crossing the road and getting struck by vehicles are at a high risk of blunt abdominal trauma. Collision with steering wheels, bicycle handles, and occasionally airbags may lead to blunt abdominal trauma. Seatbelt-unrestrained passengers are at a higher risk. Injury due to a fall from height may lead to polytrauma where blunt or penetrating abdominal trauma may result, depending upon the surface and/or object on which the victim lands.

In gunshot penetrating abdominal trauma, the severity of the injury is proportional to the bullets' mass and square of its velocity. It can be classified as *high-velocity wound* (>1,000 m/s bullet velocity), *low-velocity wound,* and *shotgun wound*. Shotgun wounds are further classified as per the injury pattern: Type I (wounds spread >25 cm and less penetrated, likely shot from >6 m), type II (spread 10–25 cm), and type III (spread <10 cm, shot from point-blank range <3 m). In addition to the injury due to the foreign object, e.g., bullet and its transmitted heat energy, secondary injury due to fragmented bones may also be present in gunshot wounds. Moreover, bullet velocity, trajectory, and direction further determine the impact of the damage.

Diaphragmatic rupture occurs most commonly on the left side and may be caused by a blunt as well as a penetrating abdominal trauma. Although a rare condition, an undiagnosed diaphragmatic rupture would leads to strangulated abdominal contents. Rectus abdominis hematomas may develop a palpable mass below the umbilicus and mimic intra-abdominal trauma.

Retroperitoneal trauma signifies any injury to the pancreas, duodenum, kidneys, ureter, and bladder. Pancreatic injuries are associated with slightly higher morbidity and mortality when compared to other abdominal trauma. Traumatic

TABLE 1: Etiology of abdominal trauma.

Blunt abdominal trauma	***Penetrating abdominal trauma***
• Road traffic accident	• Road traffic accident
• Assault, e.g., blows to the abdomen	• Assault, e.g., gunshot/firearm, stabbing
• Fall from height	• Fall from height
• Sports injury	• Sports injury
• Industrial injury	• Industrial injury

pancreatitis may lead to significant loss of third-space fluid as hours to days are passed by before shock is apparent. No specific signs or symptoms differentiate pancreatic trauma from other abdominal traumas as such; however, the mechanism of deceleration, especially in unrestrained drivers hitting steering, often causes pancreatic trauma. Duodenal rupture also results from a high-speed decelerating mechanism. Renal injury may be associated with injury to the spine, ribs, aorta, inferior vena cava, ureter, and abdomen.

Pelvic fractures can lead to >2–3 L of blood loss which may remain difficult to halt despite aggressive resuscitation. An open book fracture with symphysis pubis joint separation > 2 cm, quadripartite butterfly fracture of all four pubic rami, and Malgaigne fracture from a vertical shear force are among the pelvic fractures associated with massive blood loss.

Coagulopathy and hyperfibrinolysis occur early in major trauma. Crush injuries are possible with lax abdominal wall, e.g., in elderly and alcoholic patients. An intestinal perforation and spillage are possible in both blunt and penetrating abdominal trauma. Missed or delayed diagnoses lead to the most serious consequences in abdominal trauma. Long-term sequelae of missed renal and genitourinary injuries are hypertension, incontinence, erectile dysfunction, chronic kidney disease, and nephrectomy.

CLINICAL PRESENTATION

The most common symptoms of abdominal trauma are based on blood loss, hypotension, and shock as well as peritoneal contamination and irritation due to ruptured gastrointestinal tract, inflammation, infection, and sepsis. The most common symptom in conscious patients would be pain in the abdominal region. Abdominopelvic injuries often present with referred shoulder tip pain which should not go unnoticeable. Splenic trauma may exhibit pain over the left shoulder whereas liver trauma exhibits pain over the right shoulder. Myocardial infarction should never be missed in shoulder pain. Some patients with abdominal trauma may have focal pain during rotation, flexion, extension, or tenderness over percussion as their only positive clinical finding. Patients presenting with difficulty in breathing following abdominal trauma should be looked for diaphragmatic rupture or injury since it can be the only presenting complaint. Renal injury may present with microscopic or macroscopic hematuria and shock. Intraperitoneal bladder rupture is associated with shock and peritonism. Extraperitoneal bladder rupture leads to microscopic hematuria and hematoma. Traumatic rupture of the membranous urethra is associated with urethral bleeding, inability to void, high-riding prostate on rectal examination, and underlying tender hematoma. Traumatic rupture of bulbous urethra causes local perineal tenderness, hematoma, and meatal bleed. Missed perineal injuries may complicate with infection and fistula.

Features of Concern (Red Flags)

Hypotension is the most important red flag for all abdominal injuries irrespective of their mechanism. It may not result until at least 25–30% of the circulatory volume has depleted. Any increase in pulse pressure should be noted and is followed by a fall in hourly urine output, further followed by anxiety and altered sensorium unless the hypotension is corrected. Dizziness and fatigue are other symptoms suggestive of blood loss and should be considered as red flags for delayed bleeding in patients who are discharged from the emergency department (ED). Fever and leukocytosis are red flags in patients with a history of blunt abdominal trauma that had presented late and there could be duodenal rupture which may progress toward sepsis. Vomiting, especially of delayed onset after discharge from the ED in apparently insignificant trauma, should also be considered as a red flag for return to the ED, since its underlying cause may vary from head injury to duodenal rupture and other intra-abdominal trauma.

EVALUATION

History

Focused history includes allergies, ongoing medications, past illnesses, pregnancy, last meal status, and the circumstances leading to the injuries. If time and situation permit, a detailed history is always useful in determining the time of injury, underlying mechanism, vehicle speed, collision type (frontal impact, lateral impact, rear impact, rollover, etc.), and details of objects/weapons involved. In case of penetrating abdominal trauma, useful information includes the type of weapon, the victim's distance and position from the weapon, the estimated number of injuries inflicted, and the estimated blood loss. Inability to void should be taken seriously since it may be as a result of shock, spinal trauma, pain, or an injured ureter, bladder or urethra. Examples of dangerous mechanisms of injury are a pedestrian struck by the vehicle, victim ejected from the vehicle, fall from height, and death of fellow passengers in a road traffic accident. These should be looked for in history if witnesses are available.

Physical Examination

After a primary survey of the airway, breathing, circulation, disability [Glasgow Coma Scale (GCS), pupils, lateralizing signs, neurological deficit], and exposure, the patient should be logrolled to look for penetrating injuries over the back and perineum, thoracolumbar spine injuries, and rectal examination for tone, prostate, blood, and other injuries. This is followed by a secondary survey whereby the patient must be examined thoroughly all over the chest, abdomen, pelvis, perineum, and each region of the body.

Any visible external injury can range from abrasions, contusions, and lacerations to puncture wounds and ecchymoses (**Fig. 1**). *Periumbilical ecchymoses (Cullen's sign) and flank ecchymoses (Grey Turner sign) are suggestive of retroperitoneal hemorrhage*. Tire marks and *"seatbelt sign"* (contusion or abrasion across the abdomen) are clues to *potential blunt abdominal trauma*. In gunshot penetrating abdominal trauma, there is an apparent entry wound and an exit wound should also be looked for. Bowel sounds should be auscultated. Ileus as a result of free intraperitoneal blood may cause loss of bowel sounds.

Tenderness, distension, dullness, rigidity, and guarding should be assessed across all quadrants. Signs of peritoneal irritation are evoked by peritoneal movement due to percussion. Palpation of a high-riding prostate suggests pelvic fracture. In penetrating abdominal injuries, sometimes there may be active bleeding from wounds or evisceration of bowel loop and omentum which requires sterile wet nonadhesive dressing.

FIG. 1: Visible external injury in abdominal trauma. ***(For color version, see plate 40)***

TABLE 2: Decision-making for investigation in the abdominal trauma patient.

Clinical status and hemodynamic	*Investigation recommendations*
Mechanism of injury nondangerous, normal vital signs, and clinical assessment reassuring	Consider foregoing transfer to the trauma center and CT scan
Mechanism of injury dangerous but vital signs stable or fluctuation in blood pressure	To define the nature and severity of the injury—CT scan useful
Unstable/prearrest—blood pressure < 100 mm Hg, weak peripheral pulses/no pulse, altered mentation	*CT imaging contraindicated*, resuscitation, early surgical consultation, preparation for operation theater, consider REBOA (resuscitative endovascular balloon occlusion of the aorta), consider transfer to the trauma center

Interpretation of Finding

The accuracy of physical examination in blunt abdominal trauma is 55–65%. Up to 45% of patients with blunt abdominal trauma may have had a normal initial physical examination. The abdominal examination will be unreliable in patients presenting with intoxication, e.g., alcohol/drugs, low GCS, spinal injury, or equivocal findings due to concomitant/distracting injuries to the head, lower ribs, spine, and/or pelvis. Pelvic bone instability maneuver can be unreliable at times and risks increment in bleeding by dislodging the clots.

INVESTIGATIONS

Not all patients presenting with abdominal pain following a blunt abdominal trauma require extensive investigations. As abdominal trauma patients present with varying degrees of signs and symptoms (stable to unstable), investigations should be decided according to their hemodynamic status (choosing abdominal CT scan for hemodynamically unstable patients would be disastrous) (**Table 2**). *However, patients with the following conditions should be further evaluated by extensive investigations:* Abdominal tenderness persists after initial analgesia; abdominal distension; external visible injury; dangerous mechanism of injury as aforementioned; additional grievous trauma to head, face, thorax, pelvis, or long bones; altered sensorium; unexplained hypotension; pregnant patients; and patients at risk of bleeding, e.g., on anticoagulants or with an active liver disease.

Basic Laboratory and Point-of-care Tests

Two large-bore intravenous (IV) cannulas are inserted and blood samples are collected to be sent for a preoperative profile that includes complete blood count (CBC), creatinine, urea, and electrolytes. Liver function test (LFT), random blood sugar (RBS), amylase/lipase, blood grouping/crossmatching, prothrombin time (PT), activated partial thromboplastin time (aPTT), human immunodeficiency virus (HIV), hepatitis B surface antigen (HbsAg), hepatitis C virus (HCV), and an electrocardiogram (ECG) should be documented. Urinalysis can be missed but helps in determining hematuria. Venous blood gas analysis may be useful for assessing pH and lactate levels, and thromboelastography for clotting deficiencies. In major trauma, hematocrit gives an idea of the extent and duration of hemorrhage, leukocytosis with moderate left shift occurs within several hours, and metabolic acidosis with the increased base deficit and/or lactate is suggestive of hemorrhagic shock. Elevated serum transaminases cannot differentiate between major and minor hepatic trauma and alcohol-induced liver damage.

Point-of-care Ultrasound

Point-of-care ultrasound (POCUS) is useful in terms of focused assessment by sonography in trauma (FAST) scan or an extended focused assessment by sonography in trauma (eFAST) scan that includes assessment for pneumothoraces. Ultrasound is ideal, when patients are unstable and cannot be shifted for a CT scan. The FAST scan is a bedside, rapid, noninvasive tool that does not involve radiation or contrast material and it is very effective in detecting intraperitoneal fluid as well as cardiac tamponade and pneumothorax. At the same time, it is operator dependent and cannot detect the hemorrhage "source" and diaphragmatic/retroperitoneal injuries.

X-ray

Patients should have a chest X-ray, an X-ray of the pelvis with both hips, and a thoracolumbar spine X-ray if there is tenderness or neurological deficit. X-rays can locate metallic foreign bodies in addition to the usual findings. The chest X-ray can detect free gas under the diaphragm (if done in a semierect position after ruling out spine injury) and rib fractures with any associated pneumothorax/hemothorax. X-ray of an unstable pelvic fracture may appear normal in the presence of a well-fitted pelvic binder.

Computed Tomography

An abdominopelvic CT scan with IV contrast is considered as the gold standard in diagnosing abdominal trauma since it helps in determining the anatomy and grade of injury,

FIG. 2: Contrast-enhanced computed tomography of the abdomen showing grade IV liver injury with hemoperitoneum with contrast blush.

in quantifying the free fluid, and in detecting contusion, laceration, hematoma, and inadequate perfusion (**Fig. 2**). The CT scan demonstrates active bleeding as a blush and guides the requirement of surgery or therapeutic angioembolization. A delayed scan of KUB (kidney, ureter, bladder) helps in detecting urinary extravasation. The only major disadvantages of CT are the need to transfer the patient, radiation exposure, and a possibility of contrast allergy.

Diagnostic Peritoneal Lavage

With radiological advancements (X-rays, CT, ultrasound), the role of diagnostic peritoneal lavage (DPL) has largely been dissolved. Moreover, DPL is redundant when laparotomy is already indicated. However, it may be useful when radiology is either unavailable or unreliable and the patient shows unexplained hypotension. DPL is done by infiltrating a local anesthetic agent and epinephrine followed by a closed (using a catheter over a guidewire below the umbilicus) or open (using a small laparotomy incision through the abdominal wall layers) technique and aspiration after instilling 10 mL/kg warmed normal saline. The urinary bladder should be drained beforehand. If >10 mL of frank blood is aspirated or the lavage fluid analysis shows >100,000 red blood cells (RBCs)/mm^3, then the lavage is considered positive and thus needs surgical intervention. The procedure often provides no information regarding the source or magnitude of the bleeding and retroperitoneal injuries. A solid parenchymal damage, e.g., subcapsular splenic injury, may be missed by both ultrasound and DPL in the absence of intraperitoneal free blood. Diagnostic laparoscopy is used by some clinicians in hemodynamically stable patients. Retrograde cystography is useful in bladder injuries. Suspected urinary system injuries are evaluated using a contrast-enhanced CT scan or intravenous pyelogram (IVP). Renal angiography can detect vascular trauma.

TREATMENT

Rapid Assessment

Rapid assessment of airway and breathing is the first priority. High-flow oxygen should be given and the patient kept nil by mouth. Any wounds with active hemorrhage need compression or hemostatic dressing to control the bleed. Any exposed bowel should be covered with saline-soaked nonadhesive dressing. IV crystalloids, i.e., normal saline or lactated (Ringer's or Hartmann) solutions, should be used for initial resuscitation until blood is available. Adequate pain management, antacid and antiemetic should be given. Measures should be taken to prevent hypothermia. Antifibrinolytic tranexamic acid should be given early, within 3 hours of injury if possible.

Fluid Resuscitation

The aim of fluid resuscitation is to regain hemostasis but decrease blood loss. The damage control resuscitation concept promotes minimal crystalloids and permissive hypotension to minimize bleeding followed by a balanced transfusion of frozen plasma, platelets, and packed cell volume at the earliest. This is found to control coagulopathy and improve survival.

Serial FAST scans help in estimating the severity of intraperitoneal hemorrhage. Apart from FAST scan, ultrasound is also useful to check for inferior vena cava diameter to estimate intravascular volume, guide volume resuscitation, and also predict mortality.

Adjunct

The nasogastric tube is inserted to drain gastric contents and urethral catheter to monitor urine output. In the presence of facial or basilar skull fracture, the nasogastric tube should be inserted orally. A urethral catheter is avoided in cases of blood at the meatus which is suggestive of urethral injury, scrotal hematoma, high-riding prostate, or complex pelvic injuries. A pelvic binder sling should be applied in suspected pelvic fractures. An ultrasound-guided suprapubic catheter should be placed by an experienced clinician in case of urethral injuries. Broad-spectrum antibiotic coverage, e.g., ampicillin 1 g IV, gentamicin 5 mg/kg IV, metronidazole 500 mg IV, and tetanus prophylaxis should be given as per wound contamination and patient's history of previous tetanus prophylaxis.

Hemorrhage Control and Laparotomy

Hemorrhage control in severe abdominopelvic trauma may require laparotomy as the gold standard definitive treatment, with/without pelvic fixation. Some patients may require angioembolization for hemorrhage control if the patient is stable hemodynamically. *Indications of laparotomy* (**Table 3**) include blunt or penetrating trauma associated with persistent shock as evidenced by a positive FAST/DPL, radiological evidence of free gas under the diaphragm, diaphragmatic rupture, disrupted abdominal wall with/without evisceration, peritonitis, and CT diagnosed trauma that indicates for surgery. Any penetrating injury, such as a stab wound, gunshot, and industrial puncture wound, and hemoperitoneum without a clear source remain as relative indications for exploratory laparotomy. Hemorrhage is controlled by sequentially packing the four quadrants of the abdomen. Simple bowel perforations are repaired and in complex injuries, bowel resection may be performed. After initial resuscitation, the admitting surgical team is involved as early as possible since the decision for emergency laparotomy rests on them.

Operative versus Nonoperative Management: Role of Computed Tomography

The CT scan is useful in deciding for *operative versus conservative nonoperative management* (NOM) of abdominal trauma by providing a detailed anatomy and a severity-based solid viscera injury grading. High-resolution helical CT helps in identifying vascular injuries, aneurysms, and arteriovenous fistula. Percutaneous transcatheter coiling and temporary endovascular balloon occlusion are other examples of upcoming treatment modalities. Angioembolization is useful in evidence of active contrast extravasation on CT scan and in retroperitoneal arterial bleeding. A large vessel injury should not be missed.

Both *hepatic and splenic injuries* are graded according to the American Association of Surgery for Trauma (AAST) liver and spleen injury scale (I–V), respectively. The AAST liver and spleen injury scale 1994 revision is summarized in **Table 4**. The vast majority of patients with blunt hepatic and splenic injury require conservative NOM. Liver trauma surgery objectives are hemorrhage control, bile leak control, debridement or resection of devitalized liver, and drainage. Hepatic necrosis, abscess, bile leak, and delayed hemorrhage are the most common complications of liver NOM. Overwhelming postsplenectomy infection by encapsulated organisms and splenosis are late and rare complications of splenectomy. Pneumococcal, meningococcal, annual influenza, and *Haemophilus influenzae* type B vaccinations are recommended for postsplenectomy. A complication of spleen NOM is that any possibility of operative intervention for any associated traumatic damage would be delayed or lost with time. In the absence of a strict consensus, typically such patients are advised to refrain from activities that put them at risk of splenic trauma for a time period ranging from 2 to 6 months.

Endoscopic retrograde cholangiopancreatography is the most sensitive method for diagnosing pancreatic duct injury. Distal pancreatectomy and use of external drains have demonstrated a reduction in morbidity and mortality. Complications of conservative as well as operative treatment include pancreatitis, fistula, abscess, pseudocyst, and sepsis.

Over 85% of blunt *renal injuries* require conservative management. The AAST renal injury scale is given in **Table 5**. Generally, grades I to III require conservative management, while grades IV and V may require operative management. Renal vascular injuries require revascularization as early as possible with variable guidelines. Complications after renal trauma include delayed bleeding, urine extravasation, abscess formation, and renal failure.

Pelvic trauma is often graded using the Young and Burgess classification based on the type of force: Lateral compression, anteroposterior compression, or vertical shear. Surgical management is required in complex pelvic fractures that involve the perineum, rectum, or vagina and in intraperitoneal bladder rupture. Early involvement of the obstetric team is vital for managing abdominal trauma in pregnancy, which involves fetal ultrasound, avoidance of CT scan and X-rays

TABLE 3: Indications for laparotomy.

Absolute indications (prepare for operation theater)	*Relative indications (discuss with trauma surgeon)*
Blunt: • Grossly hemodynamic unstable patient ± FAST • Generalized peritonitis • Free air under the diaphragm on chest X-ray Penetrating: • Evisceration • Abdomen, flank, back injury with hypotension • Shotgun injury (transabdominal trajectory)	Blunt: • FAST/DPL+ve in hemodynamically stable • Liver/spleen/kidney injury hemodynamically stable • Hemoperitoneum diagnosed on CT Penetrating: • Stab wound exploration

(DPL: diagnostic peritoneal lavage; FAST: focused assessment by sonography in trauma)

TABLE 4: Liver and spleen trauma grades.

Grade	*Liver description*	*Spleen description*
I: Hematoma	Subcapsular nonexpanding, <10% surface area (SA)	Subcapsular, <10% SA
I: Laceration	Capsular tear nonbleeding, <1 cm depth	Capsular tear, <1 cm parenchymal depth
II: Hematoma	Subcapsular, 10–50% SA Intraparenchymal, <10 cm diameter	Subcapsular, 10–50% SA Intraparenchymal, <5 cm diameter
II: Laceration	1–3 cm parenchymal depth, <10 cm length	1–3 cm parenchymal depth, not involving vessel
III: Hematoma	Subcapsular, >50% SA or expanding Ruptured subcapsular/parenchymal hematoma Intraparenchymal >10 cm or expanding	Subcapsular, >50% SA or expanding Ruptured subcapsular/parenchymal hematoma Intraparenchymal >5 cm or expanding
III: Laceration	>3 cm parenchymal depth	>3 cm depth or involving trabecular vessels
IV: Laceration	25–75% of hepatic lobe parenchymal disruption or 1–3 Couinaud segments within a lobe	Laceration of segmental or hilar vessels with major devascularization (>25% of the spleen)
V: Laceration	>75% of hepatic lobe parenchymal disruption or >3 Couinaud segments within a lobe	Completely shattered spleen
V: Vascular	Juxta hepatic venous injuries, i.e., retrohepatic vena cava or central major hepatic veins	Hilar vascular injury with devascularized spleen
VI	Vascular: Hepatic avulsion	–

TABLE 5: Renal trauma grades.

Grade	*Description*
I	Hematuria with normal anatomy or subcapsular nonexpanding hematoma; no laceration
II	Perirenal, nonexpanding hematoma or <1 cm renal cortex laceration with no urinary extravasation
III	>1 cm renal cortex laceration with no collecting system involvement or urinary extravasation
IV	Laceration through cortex and medulla and into the collecting system or segmental renal artery or vein injury with hematoma
V	Shattered kidney or vascular injury to renal pedicle or avulsed kidney

unless inevitable, judicious fluid resuscitation, continuous cardiotocography, and *Kleihauer–Betke tests* to identify fetomaternal hemorrhage and immunoglobulin in rhesus negative pregnant women. Pediatric abdominal trauma management priorities and strategies are similar to those of adults.

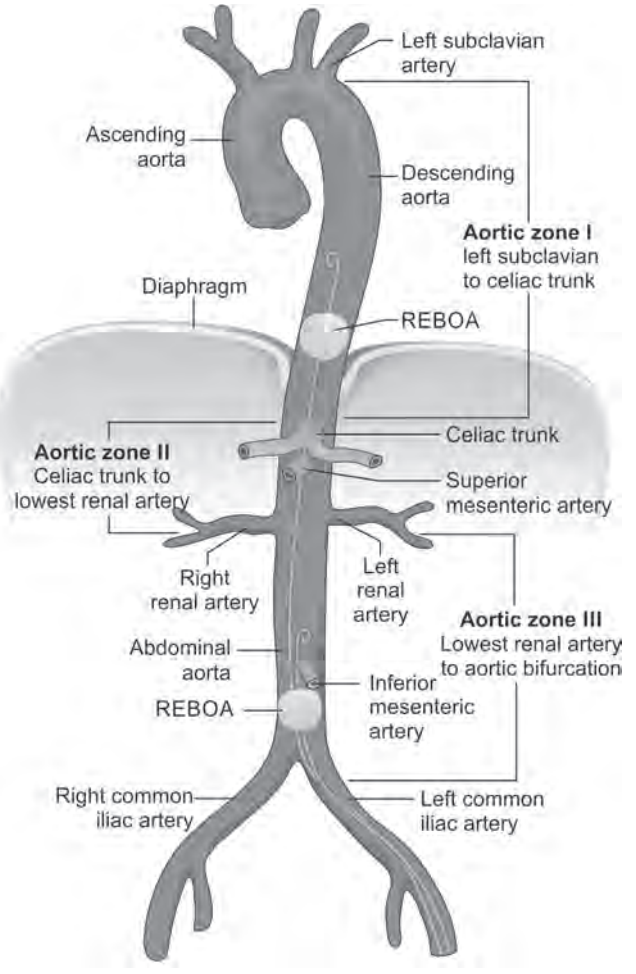
RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA

Resuscitative endovascular balloon occlusion of the aorta (REBOA) has recently come up as a minimally invasive alternative to open aortic cross-clamping in the management of the nonresponsive category of polytrauma patients. It will help in controlling noncompressible hemorrhage arising below the diaphragm. It is being used in both blunt and penetrating abdominal trauma. The use of REBOA provides for temporary hemorrhage control and improved hemodynamics until definitive surgical/endovascular control of hemorrhage is achieved.

REBOA Technique and Indications

REBOA is being used in zones I and III of the aorta (**Fig. 3**). Zone 1 of the aorta extends from the left subclavian artery to the celiac artery. Zone 2 continues from the celiac artery to the renal artery. Zone 3 extends from the origin of the lowest renal artery to the aortic bifurcation (infrarenal aorta). Zone 1 occlusion is utilized in patients with cardiac arrest or those in hemorrhagic shock with evidence of noncompressible hemorrhage arising below the diaphragm. Zone 2 is considered to be a no-occlusion zone. Zone 3 occlusion is reserved for patients without evidence of intra-abdominal hemorrhage but with evidence of a pelvic fracture.

A clinical algorithm outlining the clinical decision-making for REBOA utilization is presented in **Flowchart 1**. For decision-making, a chest X-ray (CXR) must be obtained to rule out a major thoracic vascular injury as the cause of hemodynamic compromise. If CXR is suspicious for aortic injury consistent with mechanism (widened mediastinum, apical cap, and depressed left mainstem bronchus), then REBOA is contraindicated. The FAST exam also helps in identifying the source of hemorrhage within the abdomen, along with ruling out pericardial tamponade. Patients with hypotension [defined as systolic blood pressure (SBP) < 90 mm Hg] not responsive to initial blood product resuscitation and with a positive abdominal FAST exam would be candidates for zone 1 occlusion. Patients who are hypotensive with a negative FAST exam and a pelvic fracture would be candidates for zone 3 occlusion.



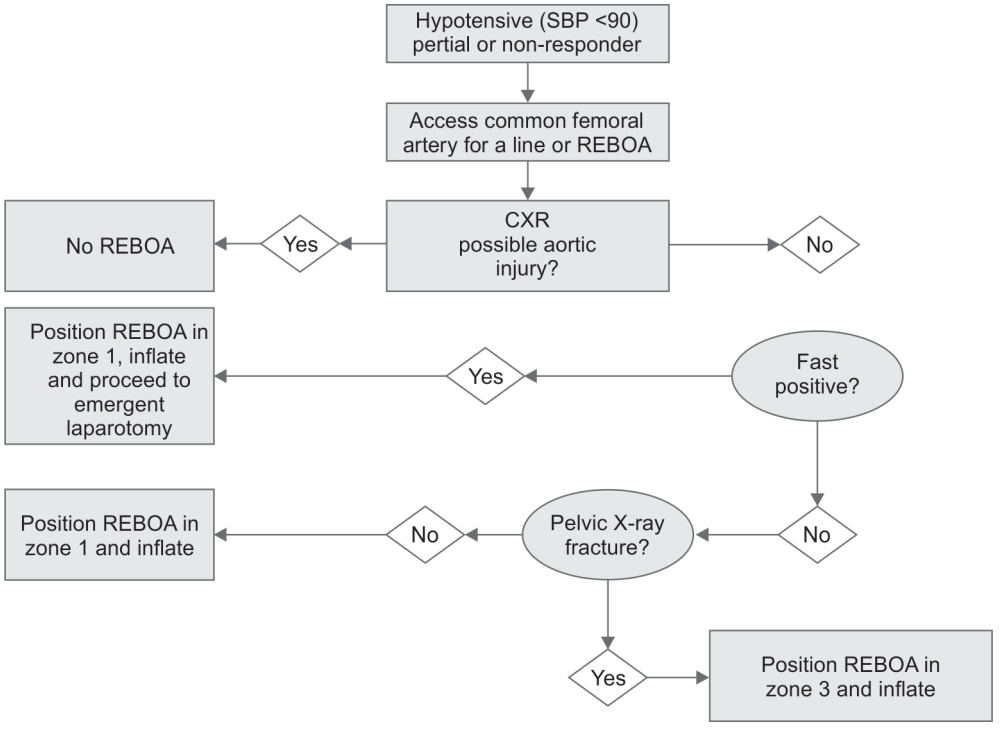
(REBOA: resuscitative endovascular balloon occlusion of the aorta)

FIG. 3: Position of balloon in REBOA.

REBOA can be divided into the following steps:

1. Arterial access with insertion of the arterial sheath (12 vs. 7 French depending on the catheter used)
2. Insertion of REBOA catheter with balloon positioning at an appropriate aortic zone
3. Balloon inflation
4. Balloon deflation
5. REBOA catheter removal
6. Arterial sheath removal

The common femoral artery (CFA) should be accessed under ultrasound guidance if available. Arterial cut-down may be required for direct visualization of the CFA in patients who are in cardiac arrest and is a more reliable method of access. Inadvertent cannulation of the superficial femoral artery has resulted in significant vascular injury and should be avoided. After the appropriately sized sheath has been placed, the aortic zone of occlusion (zone 1 or 3) must be decided based on the clinical algorithm discussed previously. Confirmation of appropriate balloon location via digital X-ray should be performed prior to balloon inflation. The catheter should be



(CXR: chest X-ray; REBOA: resuscitative endovascular balloon occlusion of the aorta; SBP: systolic blood pressure)

FLOWCHART 1: Clinical decision-making for REBOA, immediate hemorrhage control, and bridge to laparotomy.

seen on the patient's left side adjacent to the spine. Zone 1 is confirmed by visualizing the balloon above the diaphragm. Confirmation of the device in zone 3 is seen on pelvis X-ray as being in the vertical position at approximately the L2 or L3 vertebrae.

After inflation, monitoring for loss of the contralateral femoral pulse by palpation or Doppler indicates that sufficient balloon inflation has occurred. Once the device is deployed in the desired zone, it has to be secured to prevent potential complications and the time of occlusion should be noted. After balloon inflation, the patient should be sent urgently to the operating room either for exploratory laparotomy or for angioembolization. It is important to remember that REBOA is only a temporizing measure method to continue perfusion to the heart and brain en route to rapid, definitive hemorrhage control. It is emphasized that there are potential complications of REBOA related to the level and duration of balloon inflation. Overinflation of the balloon can result in either balloon or blood vessel rupture.

Once definitive hemorrhage control has been obtained, balloon deflation can occur. Incremental balloon deflation is typically required in order to avoid cardiovascular collapse. The REBOA catheter can be removed from the sheath after the balloon has been deflated. Then it is important to assess distal perfusion in bilateral lower extremities. Diminished or absent distal pulses in either lower extremity following REBOA warrant immediate investigation with angiography to identify any potential vascular complications. Neurovascular examination of the lower extremity should be done every hour for the first 24 hours after sheath removal.

The current literature regarding REBOA utilization is increasing but has been limited to large case series. The American Association for the Surgery of Trauma Aortic Occlusion for Resuscitation in Trauma and Acute Care Surgery registry has published similar findings, with a trend toward improved survival in patients undergoing REBOA compared with resuscitative thoracotomy (RT). The survival benefit is most pronounced in patients not undergoing cardiopulmonary resuscitation at the time of aortic occlusion.

The duration of occlusion remains an important factor when considering the deployment of a REBOA device. With a goal of <60 minutes of occlusion in zone 1 and ~90 minutes in zone 3, rapid access to definitive trauma/vascular surgical management is critical. The goal of REBOA is to improve survival, not prolong time to death. Partial occlusion of the aorta can be achieved by not inflating the balloon to the point of aortic occlusion.

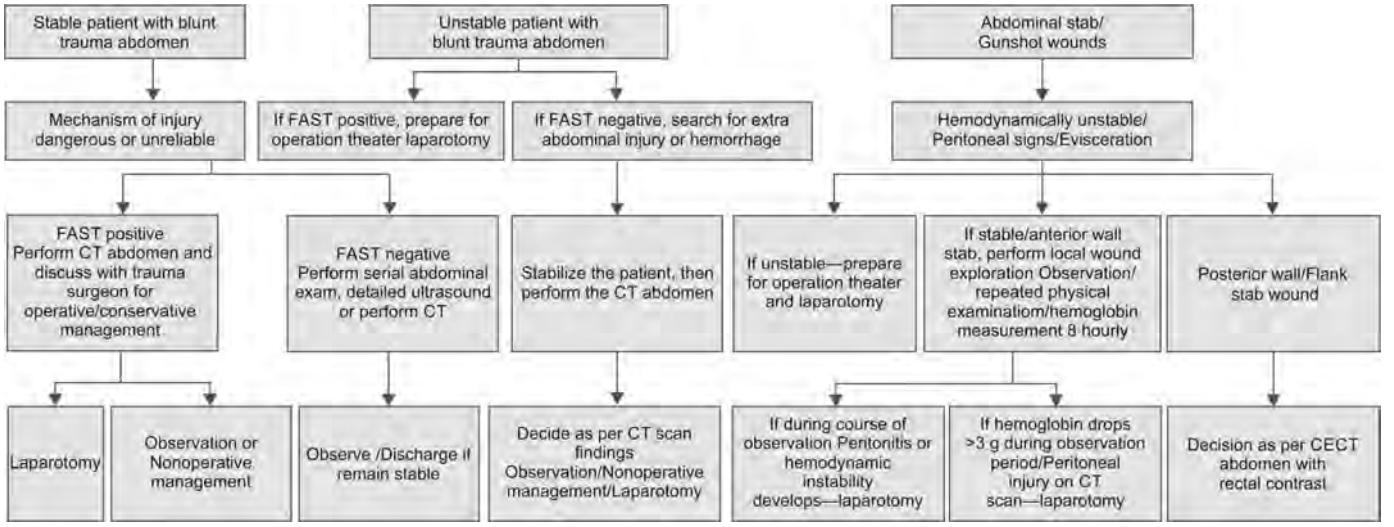
DISPOSITION

Patients with abdominal trauma require close observation and those with significant injury or hemodynamic instability require definitive surgical intervention. Patients presenting with any of the red flags such as hypotension, altered sensorium, dizziness, fatigue, fever, and vomiting should consult the ED. Complications include hemorrhage, coagulopathy, and sepsis.

SUMMARY

Abdominal trauma is not uncommon and can be blunt or penetrating. Road traffic accidents and assaults are the most common causes. Shock in trauma should raise suspicion for blunt abdominopelvic injuries since it is associated with mortality. The goal of the secondary survey is to not miss any injury, but it never foregoes the primary survey. Many a time in hemodynamically unstable patients, the primary survey may not be over in the ED but the patient goes for surgery for hemorrhage control. Hence, the primary survey

needs to complete in the intensive care unit (ICU) and so is the secondary survey. There is limited accuracy of physical examination in both blunt and penetrating abdominal trauma. Diagnostics and management go hand in hand without awaiting a detailed history or elaborate investigations. POCUS helps in identifying the presence of intraperitoneal fluid whereas CT scan is the gold standard in deciding for operative versus conservative management by quantifying the severity of injury, e.g., using the AAST organ injury scale. Severe trauma may require laparotomy, with/without pelvic fixation and angioembolization followed by intensive care and other interdisciplinary management as summarized in **Flowchart 2**.



Stable patient with blunt trauma abdomen
Unstable patient with blunt trauma abdomen
Abdominal stab/ Gunshot wounds
Mechanism of injury dangerous or unreliable
If FAST positive, prepare for operation theater laparotomy
If FAST negative, search for extra abdominal injury or hemorrhage
Hemodynamically unstable/ Peritoneal signs/Evisceration
FAST positive Perform CT abdomen and discuss with trauma surgeon for operative/conservative management
FAST negative Perform serial abdominal exam, detailed ultrasound or perform CT
Stabilize the patient, then perform the CT abdomen
If unstable—prepare for operation theater and laparotomy
If stable/anterior wall stab, perform local wound exploration Observation/ repeated physical examination/hemoglobin measurement 8 hourly
Posterior wall/Flank stab wound
Laparotomy
Observation or Nonoperative management
Observe /Discharge if remain stable
Decide as per CT scan findings Observation/Nonoperative management/Laparotomy
If during course of observation Peritonitis or hemodynamic instability develops—laparotomy
If hemoglobin drops >3 g during observation period/Peritoneal injury on CT scan—laparotomy
Decision as per CECT abdomen with rectal contrast

(CECT: contrast-enhanced computed tomography; CT: computed tomography; FAST: focused assessment by sonography in trauma)

CHAPTER

Genitourinary Trauma

Rajashekar Mohan, Lancelot Lobo, Nawin Kumar

INTRODUCTION

Genitourinary trauma, irrespective of age, has a global incidence of 10–20%, and in about 65–90% of cases, the kidney is the only organ that is injured. These injuries are about three times more common in males compared to females. Operative management (OM) remains the mainstay of management in unstable patients, sometimes after the failure of nonoperative management (NOM), and in most penetrating injuries. NOM is increasingly being utilized in stable patients at centers which have access to endovascular, endourological, and angiographic interventional facilities.

Management decisions should be based on physiological status, anatomic damage caused by the injury, and associated injuries in the patient. As general surgery and trauma surgery guidelines tend to focus on restoration of physiology whereas urology guidelines focus on organ preservation, a collaborative approach would be an ideal for optimal outcomes for the patient. The two widely used injury grading systems are: (1) The American Association for the Surgery of Trauma Organ Injury Scale (AAST-OIS) renal injury scale (**Table 1**); and (2) The World Society of Emergency Surgery (WSES) kidney trauma classification (**Table 2**). The WSES scale incorporates the AAST-OIS scale as well as the hemodynamic stability status of the patient.

MECHANISM OF INJURY

Kidney injury is commonly due to blunt trauma (90% of times) associated with rapid deceleration and rarely (1.4–3.3% of times) due to penetrating trauma usually caused by bullets or by stab. Ureter injury is rare (1%) and most occur due to penetrating injury and in about a third of cases due to blunt trauma. Ureter injury should be suspected in high-velocity

TABLE 1: American Association for the Surgery of Trauma-Organ Injury Scale (AAST-OIS) Renal Injury Scale.

Grade	*Type*	*Description*
I	Contusion	Microscopic or gross hematuria, urological studies normal
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma	Nonexpanding, perirenal hematoma confined to renal retroperitoneum
	Laceration	<1.0 cm of parenchymal depth of renal cortex with no urinary extravasation
III	Laceration	>1.0 cm of parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
IV	Laceration	Parenchymal laceration extending through renal cortex, medulla, and collecting system
	Vascular	Main renal artery or vein injury with contained hemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum that devascularizes kidney

TABLE 2: World Society of Emergency Surgery (WSES) kidney trauma classification.

	WSES grade	*AAST grade*	*Hemodynamic*
Minor	Grade I	I–II	Stable
Moderate	Grade II	III or segmental vascular injuries	Stable
Severe	Grade III	IV–V or any grade parenchymal lesion with main vessels dissection/occlusion	Stable
	Grade IV	Any	Unstable

(AAST: American Association for the Surgery of Trauma)

impact, in deceleration injury with multiple organ system involvement, and in penetrating wounds of the abdomen. The bladder is injured more commonly following blunt injury (65–86%) than following penetrating injury (14–35%). Coexisting pelvic fracture is found in the majority of patients (60–90%) with bladder injury. Urethral injuries are uncommon and occur mostly in males following direct blunt trauma. Urethral injuries in females are usually noted to occur in association with rectal and vaginal trauma.

EVALUATION AND CLINICAL FEATURES

The initial assessment should be as per the *advanced trauma life support* (ATLS) protocols. Relevant history should include the mechanism of injury, history of previous interventions in the genitourinary tract, and any congenital anomalies.

Injury to the genitourinary system should be clinically suspected if there is: (1) blood at the tip of the urethral orifice, (2) hematuria, (3) contusion over the flank, (4) fracture of lower ribs, (5) fracture of the lower thoracic or lumbar spine, (6) pelvic fracture, (7) perineal hematoma, and (8) retention of urine. It would be wise to remember that in children, the kidneys tend to get injured easier than in adults because of anatomical factors such as less perinephric fat padding, thin abdominal wall, nonossified ribs, proportionally larger size of the kidney, and fetal renal lobulations.

INVESTIGATIONS

Urine Analysis

Either microscopic or macroscopic hematuria will be present in the majority of patients (88–94%) with injury to the genitourinary system, but this does not correspond with the injury grade of injury. Macroscopic hematuria would be highly suggestive of major renal parenchymal injury; the same may also be noted in injuries to the pelviureteric junction and injuries to the renal hilum. Rarely (0.1–0.5%), microscopic hematuria and hemodynamic stability can occur in spite of major genitourinary tract injury.

Radiological Imaging: Ultrasound

The choice of imaging is dictated by the hemodynamic stability of the patient. In a hemodynamically unstable patient, the only imaging that may be feasible is the extended focused assessment with sonography in trauma (eFAST), which is useful to rapidly detect free fluid in the abdominal cavity but has poor sensitivity and specificity in detecting genitourinary injuries. Conventional ultrasound frequently underestimates renal injuries and even with a Doppler ultrasound, vascular injuries may remain undetected. Contrast-enhanced ultrasound (CEUS) shows promise in detecting extravasation and vascular damage, but it is not still widely available for use.

Radiological Imaging: Computed Tomography

In hemodynamically stable patients, intravenous (IV) contrast-enhanced computed tomography (CECT) is the standard evaluative modality for assessment of blunt as well as penetrating injuries to the genitourinary tract. This should be done with an arterial phase at 20–30 seconds, a venous phase at 70–80 seconds, and a delayed (excretory) phase at 5 minutes, to visualize the entire genitourinary system. CECT helps in identifying requirement for operative intervention such as contrast extravasation, perinephric hematoma of size 3.5 cm or more, medial tears with the urinary leak, and absence of contrast entering into the ureter. Perinephric fat stranding, perinephric hematoma, contrast extravasation into the perinephric space, and low-density fluid accumulation around the ureter are features suggestive of ureteric injury.

Intravenous Urography, Excretory Urethrography, Retrograde Urethrography

Although in many centers, IV urography has been replaced by computed tomography (CT) scanning, it can be useful for evaluating renal injuries detected intraoperatively, in an unstable patient. It is also useful in situations where CT scan facility is not available. Excretory urethrography is useful in evaluating patients with injuries to the perineum and bladder and those with isolated urethral injuries. Retrograde urethrography can be used to evaluate for urethral injuries intraoperatively or prior to urethral catheterization in suspicious cases.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is useful in the evaluation of renal injury in the pregnant woman, in the pediatric age group to minimize radiation exposure, in patients with iodinated contrast allergy when CECT image findings are indefinite, and in the follow-up of cases to avoid repeated radiation exposure.

TREATMENT OPTIONS

Renal Injuries: Nonoperative Management

General principle of non operative management are round the clock availability of close clinical assessment, facility for appropriate interventions, investigations, monitoring in appropriate level of care and blood bank. NOM should be applied in a graded manner from medical management toward further minimally invasive interventions by endoscopic or angiographic techniques, as appropriate. In general, NOM has similar complication rates to OM, but NOM results in better chances of preserving the kidneys and faster discharge from the hospital. For decision on planning NOM, a CECT is mandatory for defining injuries and hence NOM is feasible only in the hemodynamically stable patient. In the absence of a facility for CECT, in hemodynamically stable patients, other imaging modalities such as IV pyelography and ultrasound may be used to grade the injuries, but these are not as reliable as CECT due to high false-negative rates. The inability to appropriately image the patient due to hemodynamic instability itself is an indication for explorative OM. The same general principles as in adults apply in children too. While deciding on NOM, facilities and expertise available at hand should be considered and may by itself be a limiting factor in applying NOM in austere settings.

Many findings such as fragmented kidney, perinephric hematoma, associated renal pelvis transection, and complications of NOM such as urinomas are not absolute indications for operative intervention, and these may be managed by percutaneous, endoscopic, and angioembolization techniques, especially in the absence of any other indication

for surgery. Although isolated penetrating injuries to the kidney are rare in patients who are hemodynamically stable with isolated renal injury, NOM may be attempted. Hemodynamically unstable patients with renal injury should undergo OM.

Renal Injuries: Angiography and Angioembolization

Hemodynamically stable patients with contrast extravasation from the arterial system on CECT, ongoing gross hematuria with continuing fall in hemoglobin, post-traumatic arteriovenous fistula, and pseudoaneurysm formation are indications for angiography and selective angioembolization. The requirement for angioembolization does not correlate with the grade of renal injury, but success rates decrease with increasing grades of renal injury. In about 30% of patients with arterial contrast extravasation on CECT, there is no bleed detected on angiography. Stable patients undergoing angioembolization have a shorter length of intensive care unit (ICU) stay compared to stable patients undergoing nephrectomy.

Renal Injuries: Operative Management

Hemodynamically unstable patients with renal injury should undergo OM. Hemodynamically unstable patients, due to ongoing active bleed caused by avulsion of renal pedicle, expanding or pulsatile retroperitoneal or perinephric hematoma, and injury of the renal vein with non-self-limiting bleed, are indications for OM. In the hemodynamically unstable patient, an incidentally detected expanding or pulsatile retroperitoneal hematoma requires exploration, especially if no other cause of hemodynamic instability is detected during the laparotomy. Penetrating injuries to the kidney with associated retroperitoneal hematoma should be explored. Exploration in patients with associated arterial or renal parenchymal damage often results in nephrectomy. In patients with only one kidney or if both kidneys are injured, arterial repair should be attempted. Hemodynamically stable patients with a failed NOM technique are candidates for delayed OM.

When deciding on exploration and assessment for renal injury, thought should be given on the appropriateness of timing, especially in damage control scenarios. If exploration is being performed in patients where no preoperative imaging was feasible, the opposite kidney should be assessed for its presence and structural integrity by palpation. If feasible, an on-table IV pyelogram with excretory films can be carried out. Exploration of the kidney can be done by a pedicle first approach or by an anterior vertical incision on Gerota's fascia. Vascular pedicle control is essential for optimal assessment and repair of the renal parenchyma. The renal pedicle can be accessed directly by incising the posterior peritoneum lateral to the aorta on the affected side to expose and loop individual vessels, followed by medial reflection of the overlying colon to approach the kidney. Alternatively, the pedicle can be approached by medially reflecting the overlying colon on the affected side. Isolated vessels may be individually clamped or digital compressive pressure can be applied on the renal pedicle or parenchyma to control bleed. In general, renal preservation rates are much higher when pedicle control is achieved prior to addressing renal parenchymal injury. In the presence of a retroperitoneal hematoma, achieving pedicle control by central dissection and clamping is essential. Complete mobilization of the kidney is required for complete visualization and assessment.

Decision on renal preservation versus nephrectomy should be made at initial exploration, based on the hemodynamic stability of the patient, quantity of viable parenchyma, and extent of damage to the central vascular pedicle and ureter. In an unstable patient with a salvageable kidney, intraparenchymal bleeders can be sutured with absorbable sutures, and the kidney packed behind sterile pads, and definitively addressed after addressing other intra-abdominal injuries. If other injuries require a second procedure, the kidney may be reassessed and definitively addressed at that time. Repair of the renal collecting system can be without an internal stent if the approximation is complete, but if the approximation is incomplete or under tension, it will require an internal stent placement or nephrostomy to prevent urinoma formation. If parenchymal damage is over the poles of the kidney, a partial nephrectomy using a guillotine technique may be performed with suture closure of vessels and collecting system. Parenchymal defects can be addressed by capsular suturing whenever feasible.

If the kidney is deemed nonsalvageable based on the extent of destruction of parenchyma or vascular pedicle, a nephrectomy should be performed. While performing the nephrectomy, whenever feasible, the renal artery and vein as well as accessory vessels should be ligated separately to avoid arteriovenous fistula formation. The ureter as well as the vessels are ligated close to the kidney.

Urinary Tract Injury: Ureter

Ureteric contusions can be managed conservatively by close observation, especially if there is no other indication for laparotomy, by close observation. They may require stenting if there is an impairment in the drainage of urine. Partial transection of the ureter will require stenting. If stenting is not feasible, a diverting nephrostomy should be carried out.

In the hemodynamically stable patient, during operative intervention for other indications, if the ureteric injury is suspected, direct inspection by visualization of the ureters is necessary. Injury to the ureter noted during direct visualization should be repaired primarily. Partial transection of the ureter should be primarily repaired over a double "J" stent, or, if the injury is located distally, by implantation into the bladder. If there is complete transection of the ureter, it should be repaired primarily by ureteroureterostomy or by ureteral reimplantation by bladder psoas hitch or a Boari flap technique. Complete transection injuries to the distal ureter result in tenuous vascularity at the transected ends and should be managed by reimplantation into the urinary bladder as a ureteroneocystostomy. To ensure proper healing and to minimize leak and stricture formation at the repair site, all ureteric repairs should be done over a ureteral stent. In the hemodynamically unstable patient or if primary repair is not feasible, damage control can be achieved by tying up the ureter, with urinary diversion achieved via a temporary nephrostomy, followed by delayed definitive repair after stabilization.

In patients in whom partial ureter injury is recognized late, retrograde stenting should be carried out, and if this is unsuccessful, percutaneous nephrostomy followed by delayed

surgical repair should be carried out. If patients in whom complete ureter transection is recognized late, percutaneous nephrostomy followed by delayed surgical repair should be carried out.

Urinary Tract Injury: Urinary Bladder

Contusion of the urinary bladder requires no specific treatment. All penetrating injuries to the bladder, intraperitoneal rupture of the bladder, and complex extraperitoneal rupture of the bladder will require surgical exploration with a thorough assessment of the adjacent pelvic organs such as the rectum and vagina, followed by primary surgical repair. Rectal injury may require primary repair or diversion stoma, and vaginal injuries may require to be repaired primarily. Uncomplicated and isolated extraperitoneal bladder blunt or penetrating injury can be managed conservatively with clinical observation, under antibiotic coverage, with urine drainage by a transurethral or suprapubic catheter, avoiding an initial operative intervention. Patients with extraperitoneal bladder injury with persistent urinary extravasation beyond 4 weeks after the injury will require surgical repair.

Transurethral catheterization and drainage are as effective as suprapubic cystostomy and should be the preferred choice of drainage whenever feasible. Routine drainage of the bladder by suprapubic cystostomy should be avoided and only performed in situations when transurethral drainage is to be avoided such as in urethral and perineal injuries.

In the hemodynamically stable patient with intraperitoneal rupture of the bladder or who has sustained a penetrating injury to the bladder, exploration with primary surgical repair should be carried out, at the earliest. If intraperitoneal bladder rupture is the only injury with no other intra-abdominal injury, this can be carried out by laparoscopy. Patients with complex extraperitoneal bladder injury such as to the bladder neck, or with coexisting pelvic ring fracture, or injuries with coexisting vaginal or rectal injuries should undergo exploration with primarily repair. This can be carried out during the laparotomy for associated injuries or while exposing the prevesical plane for pelvic fixation.

In the hemodynamically unstable patient with associated bladder injury, temporary drainage of urine can be achieved by transurethral catheterization or by suprapubic cystostomy until the patient is optimized for surgical repair. During damage control procedures in the unstable patient with other organ injuries, temporary urinary diversion can be achieved through the bladder and exiting via the perivesical space or by means of an external ureteric stent.

Conventional repair of the urinary bladder is in double layers using absorbable sutures, while laparoscopic repair is usually in a single layer. Following surgical repair, all adult patients should have continuous drainage by a transurethral catheter until complete healing of the repair is achieved. Following surgical repair in children, suprapubic cystostomy is preferred for continuous drainage until healing is achieved. Healing occurs by 10 days in majority of patients.

Urinary Tract Injury: Urethra

Urethral injuries are relatively uncommon, occur more frequently in males, and usually result from blunt injuries. In women, injury to the urethra is uncommon and results from pelvic injuries. *Clinically, urethral injury should be suspected,* if the patient has blood present at the external urethral meatus, fullness in the suprapubic region, a palpable and distended bladder, urinary retention, evidence of perineal bruising or laceration, scrotal hematoma, high riding prostate on per rectal examination, and difficulty or inability to place a transurethral urinary catheter. Clinical assessment should include rectal and vaginal examination as there may be coexisting vaginal or rectal injuries.

Urethral injuries can be broadly divided into (1) anterior injury involving penile and bulbar regions, and (2) posterior injury involving prostatic or membranous regions. Posterior urethral injuries are further subclassified into complete and incomplete. In the complete subtype, there will be a gap between the two transected ends. The widely used classification for urethral injuries is the Goldman classification, which classifies urethral injuries into five types differentiating extent of transection, anatomic location, and involvement of bladder. In approximately 20% of cases, coexisting urethral and bladder injuries are noted. Anterior urethral injuries usually result from blunt trauma and rarely from penetrating trauma. Posterior urethral injuries usually result from pelvic trauma with pelvic fractures, and the majority tend to be complete injuries. In patients with pelvic fractures, the chance of associated injury to the urethra increases by approximately 10% for each 1 mm of pubic diastasis. Penetrating injury to the posterior urethra is rare, commonly as a result of gunshot wounds; hence, there can be associated intra-abdominal injuries.

Evaluation of urethral injuries can be done by retrograde urethrography or by flexible urethroscopy. In the hemodynamically stable patient, evaluation should ideally be done by retrograde urethrography and should precede other evaluative interventions. In the hemodynamically unstable patient with clinical evidence of urethral injury, urinary drainage should be performed by suprapubic catheterization, with delayed investigative assessment. Once the patient is stable, evaluation of the urethra should be carried out by urethrography, prior to transurethral catheterization. Although extravasation of contrast on urethrography indicates injury, the anatomic description may be difficult. If the patient is undergoing laparotomy for other injuries, direct assessment by flexible urethroscopy may be feasible in some patients. In women and in males with penile injuries, flexible urethroscopy is preferable over retrograde urethrography. Assessment of urethral injuries in the recovery period can be achieved by MRI of the pelvis, which will provide accurate anatomic details of the injury.

In patients in whom there is evident urethral injury or if there is clinical suspicion of urethral injury, urinary bladder drainage must be achieved at the earliest. In stable patients, a urethrogram should be carried out as soon as it is safe and technically feasible. If there is no contrast extravasation, transurethral catheterization may be carried out. However, if urethrography is not technically feasible safely, suprapubic drainage should be performed. An attempt at endoscopic realignment should be made in all cases, and if this is not successful, surgical repair with urethroplasty should be carried out. Penetrating injury to the urethra will require operative assessment and appropriate surgical correction.

In blunt injury to the anterior urethra, the initial management is on conservative lines, by transurethral or by suprapubic drainage, followed by a delayed accurate delineation of

injury and definitive repair. In some cases of anterior partial penetrating injuries, transurethral catheterization may be feasible. Isolated, uncomplicated penetrating injuries may be primarily repaired. In unstable patients, those requiring other urgent interventions, if anastomotic urethroplasty is not possible due to a large urethral defect, urethral marsupialization with suprapubic drainage followed by delayed reconstruction with a graft or flap after 3 months is advisable.

Blunt posterior urethral injuries and partial urethral transection injuries can be managed by suprapubic drainage or by transurethral drainage. Penetrating injuries to the posterior urethra will require operative assessment and appropriate repair. As primary repair or open realignment has a high incidence of stricture formation, a high incidence of urinary incontinence, and impotence, it is better to initially address this type of injury by suprapubic or transurethral drainage, planning definitive repair after 14 days. In stable patients with isolated complete posterior urethral injuries, urethroscopic realignment produces better results than immediate primary repair. When urethroscopic realignment is not feasible, suprapubic drainage followed by delayed urethroplasty may be planned, ideally to be carried out within 14 days. If there is a coexisting fracture of the pelvic ring, definitive repair must be delayed until after the fracture has healed. Penetrating injuries in stable patients with no serious associated injuries can undergo immediate retropubic exploration with primary repair. In unstable patients with other serious associated injuries undergoing damage control management, urinary diversion via a suprapubic catheter with planned delayed urethroplasty should be the plan. In the follow-up period, reassessment urethrography should be done once in every 2 weeks until complete healing is achieved.

Pelvic hematoma or an empty bladder due to hypovolemic shock may cause difficulty in performing suprapubic drainage, and in such situations, transurethral catheterization can be attempted by an experienced person. If this is not feasible, bladder drainage can be performed by direct exposure or under guidance using ultrasound.

Renal and Urinary Tract Injuries: Review Assessment

Mild injuries to the genitourinary tract do not require routine follow-up imaging. No follow-up imaging is required in moderate injuries with no associated urinary extravasation, except if there is deterioration in the clinical condition. In severe renal injuries, a follow-up CECT with a delayed excretory phase may be required 48 hours post admission, as urinary extravasation can be missed in a small number of patients during the initial imaging. There is risk of secondary hemorrhage caused due to rupture of pseudoaneurysm or arteriovenous fistula in about 25% of patients following moderate or severe renal trauma and usually manifests as hematuria within 2 weeks following trauma. Further evaluation by CECT or Doppler ultrasonography (USG) or CEUS will be required in those patients. In pediatric patients with moderate or severe renal injury, follow-up imaging can be adequately performed by USG or CEUS. If there is suspicion on these imaging modalities, or if they are inclusive, MRI can be utilized. Following renal injuries, return to normal activity is advised only after resolution of gross hematuria, and return to sports activities until microscopic hematuria is resolved.

SUMMARY

The management of genitourinary trauma poses peculiar challenges due to the variable anatomical, physiological, and functional characteristics of its components. Often, attention to these structures is diverted by more serious injuries to the adjacent organs and it is regained only at a later stage in the management. Most of these injuries can be managed conservatively by minimal interventions, with delayed definitive repair.

229 CHAPTER

Extremity Trauma and Crush Injury

M Shiva Reddy, Rammohan Radhakrishnan

INTRODUCTION

Musculoskeletal injury constitutes a major part of emergency care. With increasing motor vehicle accidents, sporting activities, and aging population emergency departments receive a variety of injuries which demand early recognition, stabilization, care, and referral to the concerned departments for definitive care.

Prehospital care and triage: Successful optimization and treatment of a patient with musculoskeletal trauma require dedicated teamwork which starts from the site of the accident by the paramedical staff and their ability to assess, triage, and initiate critical interventions such as cervical collar, pelvic binder, tourniquet application, intravenous (IV) infusion to stabilize and to communicate with the hospital so that necessary preparation is done to optimally treat the patient.

Triage at the hospital: At the emergency, proper triage is done where a focused assessment of the traumatized patient is carried out using the START (simple triage and rapid treatment) system or color-coding system to get the right patient to the right place at the right time. The patient received in the emergency is undressed and initial survey, intervention, and resuscitation are carried out according to the advanced trauma life support (ATLS) protocols and assessment is made whether the patient's injuries and condition fall into life-threatening, limb-threatening, urgent semielective and elective group of injuries. Anatomical scoring systems such as abbreviated injury scale and injury severity score and physiological scoring systems such as Glasgow coma score and revised trauma score are used to assess the condition of the patient and help in triage.

Primary survey and resuscitation: Signs of shock such as agitation, confusion, cold extremities, weak distal pulses, decreased urine output, hypotension, and the deadly triad of metabolic acidosis, coagulopathy, and hypothermia should be aggressively treated with necessary transfusions [fresh frozen plasma and red blood cell (RBC) 1:2, platelets and RBC 1:5] and interventions. Pelvic fractures recognized on plain radiographs with an associated crush injury in the vicinity with the patient in shock not responding to the resuscitation should be treated immediately with the pelvic binder or external fixator and should be planned for emergency laparotomy and pelvic packing or angiography and embolization.

MANGLED EXTREMITY CARE

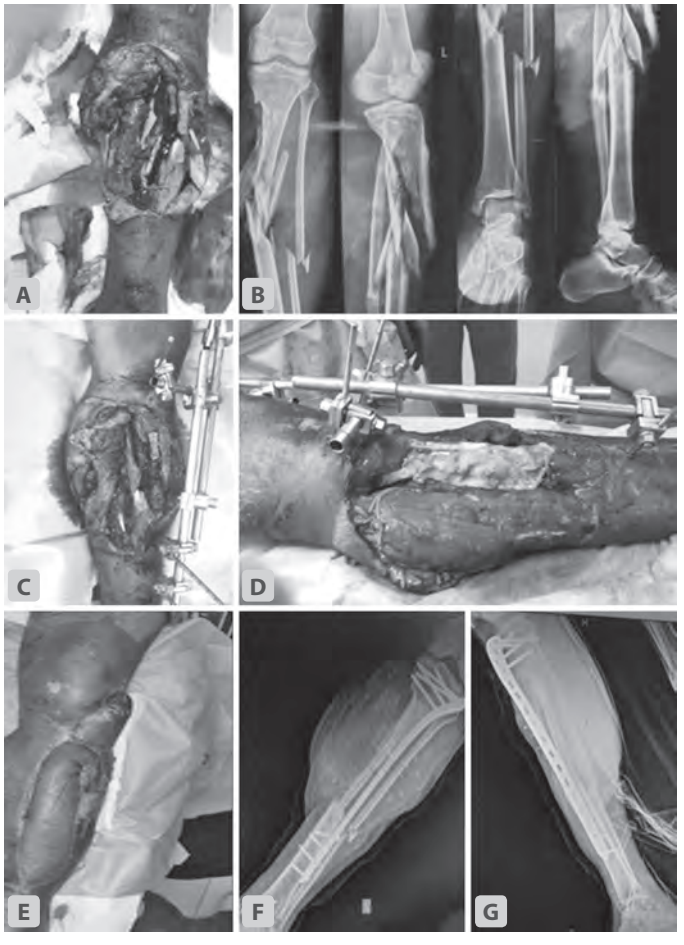
Skin and soft tissues provide the necessary milieu, cover, and protection for the bone and neurovascular structures and their management determines limb salvage versus amputation. Mangled extremity is classified using the *Tscherne classification* of closed fracture and soft tissue (**Table 1**) and *Gustilo–Anderson classification* in case of open fracture/compound injuries (**Table 2**). *All open wounds are inspected for* the degree of soft-tissue injury, presence of comminuted and segmental fractures, degree of contamination, time since injury, proximity and involvement of the joint, exposed bone and tendons, and involvement of neurovascular structures (**Figs. 1A** to **G**). All injuries, both closed and open, associated with comminuted and segmental fractures should

TABLE 1: Tscherne classification of closed fracture and soft-tissue injury.

Grade	*Presentation*
Grade 0	No or minor soft-tissue damage, indirect injury with simple fracture
Grade 1	Superficial abrasion or skin contusion, medium severity fracture pattern
Grade 2	Deep contaminated abrasion with skin or muscle contusion, severe fracture pattern by direct trauma
Grade 3	Extensive skin contusion, crush injury with severe damage to the underlying muscle, compartment syndrome, vascular injury complex fracture pattern

TABLE 2: Gustilo–Anderson classification of open bone fractures.

Grade	*Description*
Grade I	Clean skin contusion < 1 cm, usually from inside to outside > minimal muscle contusion > simple transverse or short oblique fracture
Grade II	Laceration > 1 cm long, with extensive soft-tissue damage, minimum to the moderate crushing component, simple transverse or short oblique fracture with minimal comminution
Grade III	Extensive soft-tissue damage including muscle, skin neurovascular structure, often by high-velocity/energy injury with severe cursing components
Grade IIIA	Extensive soft-tissue laceration, adequate bone coverage, segmental fracture, gunshot injuries, minimal periosteal stripping
Grade IIIB	Extensive soft-tissue injury with periosteal stripping and bone exposure requiring soft-tissue flap closure, mostly associated with massive contamination
Grade IIIC	Vascular injury requiring repair



FIGS. 1A TO G: (A and B) Severely mangled extremity with comminuted fracture; (C) Clinical picture after thorough debridement and knee spanning external fixator; (D) Bone loss spaced with antibiotic bone cement; (E) Post soft-tissue reconstruction; (F and G) X-rays showing good incorporation of the vascularized fibular graft. Compartment pressure measurement should be done in the case of comatose patients. ***(For color version, see plate 40)***

be examined periodically for pain out of proportion, pain with passive stretch, pulselessness, paresthesia, and pallor for compartment syndrome and treated with necessary fasciotomies (**Figs. 2A** to **E**).

INITIAL CARE OF THE WOUND

Initial care of wound consists of *control of hemorrhage*— by pressure bandage ligation of larger vessels (**Figs. 3A** to **F**) and *removal of gross contamination* and foreign bodies. Definitive debridement cannot be done at the trauma bay, but gross contamination and devitalized tissue can be removed by *irrigation with normal saline*. It dilutes the contamination and helps in prevention of infection and better assessment of the injury and devitalization. *Reduction of the obvious fracture deformities and dislocations*—this relieves the tension in the neurovascular structures and soft tissue around the joint and reduces the risk of infection in case of open wounds and avascular necrosis (AVN). *Approximation of wounds with large flaps with holding sutures*, *adequate dressing*, and normal saline dressing with adequate pads are important. *Stabilization with splinting*—stabilization helps in controlling the movement at the fracture site and helps in patient transport and prevents further damage to the tissue. *Initiation of broad-spectrum antibiotics*: first-generation cephalosporins for gram-positive coverage and aminoglycosides are added for gram-negative coverage; tetanus toxoid and immunoglobulins should be given as per requirment. *Adequate investigations*—bedside Doppler, ankle-brachial index, angiography rays, computed tomography (CT) with reconstruction. Communication with an orthopedician and plastic and vascular surgeons for definitive management is done.

Secondary Survey

Once the life-threatening injuries are addressed, a secondary survey from head to toe is carried out with a detailed history of the nature of the injury, speed of the collision, last meal, allergies, bleeding diathesis, and medications for medical comorbidities. Patients are shifted to the operation theater or intensive care according to the hospital protocols and patients' condition for the respective departments to continue the further evaluation and treatment.

EXTREMITY TRAUMA

Proper recognition of morphology of fracture and its classification helps in recognition of the forces involved, extent of the soft-tissue injury, planning the treatment, communication, and prognosis of the offered treatment.

Shoulder Girdle and Humerus

The shoulder joint consists of sternoclavicular acromioclavicular glenohumeral joints and scapulothoracic articulation. Shoulder injuries result due to direct fall, traction injuries, high-velocity road trauma resulting in fracture-dislocations, brachial plexus injuries, and scapulothoracic dissociation. Patients presenting with shoulder girdle injuries require prompt neurovascular examination and trauma series X-rays [anteroposterior (AP), scapular Y view, and axial view].

FIGS. 2A TO E: (A and B) Right proximal tibial fracture with impending compartment syndrome; (C to E) Application of spanning external fixator, two incision lower limb compartment release. ***(For color version, see plate 41)***

Courtesy: Dr Kesavam.

Sternoclavicular Dislocations

Anterior (common) and posterior (rare) dislocations require prompt attention and treatment because of the close proximity of vital neurovascular structures. Patients can present with dysphagia and difficulty in breathing. Serendipity view and CT scan help in assessment. Posterior dislocation needs early recognition and reduction with the help of orthopedic and thoracic surgeons. Postreduction the joint is stable and can be managed with arm sling for 3–4 weeks followed by range of motion (ROM).

Clavicle Fractures

10% of all fractures result from falls and sporting injuries. These are classified into medial third 5%, middle third 80%, and lateral third 15% depending on the location. Most of the clavicle fractures can be treated with arm sling. Segmental, displaced fracture with tenting skin, floating shoulder, and open injuries with exposed bone warrant surgical fixation.

Acromioclavicular Injuries

Acromioclavicular joint injuries result from falls directly over the shoulder. Injuries range from simple sprains to frank dislocations resulting from coracoclavicular and acromioclavicular ligament injuries. Trauma series X-ray shows vertical displacement of >100% and posterior and subcoracoid displacement needs ligament reconstructive surgery.

Shoulder Fracture-dislocations

Anterior dislocations result from abducted and externally rotated force with capsulolabral detachment (**Figs. 4A** to **D**). Bankart's lesion in young adult occurs due to fall with an outstretched hand and in older patient resulting in fracture-dislocation. Along with trauma series X-rays, the west point view shows anterior glenoid fractures and the Stryker notch view shows the extent of the Hill–Sachs lesion. CT scans are taken in selected patients with complex fractures and to evaluate the glenoid and humeral head. These dislocations should be reduced at the earliest with various techniques which involve traction and counter traction leverage and shoulder manipulation. Physicians should be well versed with more than one technique. 5-10% of fracture-dislocation cannot be reduced in the emergency room (ER) and will require general anesthesia. Reduced shoulders are immobilized in an arm sling for 1–2 weeks followed by physiotherapy. Complications include fractures, axillary nerve injury, rotator cuff tears, AVN, and recurrence. Patients with

FIGS. 3A TO F: (A) Left arm-twisting injury while trying to bend the iron rod in the machine. Note the broken arm encircled around the iron rod. (B) After a thorough wash. Bankart lesion and Hill–Sachs lesion present with recurrence and need early arthroscopic repair.

Posterior dislocations are uncommon, easily missed, and commonly occur in patients with seizures. Trauma series X-ray reveals light bulb sign with loss of overlap of normal glenoid and humerus in the AP view. In the absence of fracture and locking, closed reduction can be attempted in emergency under sedation with traction disimpaction. Postreduction is immobilized with arm sling and advised orthopedic follow-up. Complications: Fractures and missed posterior dislocations can present with pain and restricted external rotation which need open procedures. Inferior dislocations are very rare and present with a forward flexed arm. Multiple attempts may be needed if there is buttonholing of the capsule.

FIGS. 4A TO D: (A) X-ray showing humeral head fracture with anterior dislocation; (B and C) Images showing displaced fracture with reduced dislocation; (D) After definitive fixation.

Courtesy: Dr Kesavan.

Scapulothoracic Dissociation

This is very rare resulting from high-energy traction injury and occurs in multiple injured patients. A high index of suspicion is needed in the presence of hematoma in the axillary region and increased distance between the medial borders of the scapula on the chest X-ray. These injuries are associated with neurovascular injuries and dislocations around the shoulder girdle. Magnetic resonance imaging (MRI) confirms vascular and neurologic injuries.

Proximal Humerus Fractures

Proximal humerus fractures are more common in older adults with osteoporosis and result in fall on outstretched hands. Fractures are classified based on the number of fracture fragments and displacement. Most of the fractures are minimally displaced and can be managed conservatively with an arm sling. Three-part and four-part fractures are treated with open reduction internal fixation (ORIF). Displaced comminuted fracture-dislocations can result in AVN and are treated with hemiarthroplasty or reverse shoulder replacement.

Humerus Fractures

They have bimodal distribution; in the young, these fractures are commonly associated with motor vehicle accidents in the elderly, these are because of trivial falls associated with osteoporosis and pathological fractures (unicameral cysts, primary and metastatic malignancies). Orthogonal X-rays and soft-tissue and neurovascular assessment should be done and documented. Midshaft and long spiral fractures are associated with radial nerve palsy with wrist drop and weakness in finger extension and disturbed sensation. Most of the fractures can be treated with U-slab of plaster of Paris (POP) followed by functional brace. <1 cm shortening and 20–30° of angulation are accepted. Bilateral fractures, floating segmental fractures, and open injuries with neurovascular injuries are treated with ORIF. Complications are delayed union, nonunion, radial nerve palsy, and wrist drop.

Elbow and Forearm

Elbow and forearm trauma result from motor vehicle accidents, fall onto an outstretched hand (FOOSH), and side-swipe injuries and constitute 0.5% of all fractures. Orthogonal X-rays with traction help to delineate the fractures and plan management. Special attention is paid to the soft tissue and neurovascular examination. Distal humerus fractures can be divided into supracondylar, single-column, bi-column, and coronal shear fractures. Supracondylar fractures are more common in the pediatric population comprising 5–10-year age group and can be divided into extension type (98%) and flexion type (2%). Distal pulse along with neurology has to be checked at regular intervals. Anterior humeral line and Bauman's angle are used to evaluate fracture angulation and displacement in the X-rays. Minimally displaced fractures can be reduced and splinted with POP application with flexion not exceeding 70–90°. With absent distal pulse reduction and manipulation of the displaced and malrotated fractures under sedation can be attempted in the emergency with prompt orthopedic and vascular intervention at the earliest. Single-column and bi-column fractures of the distal humerus are more common in the 50–60-year age group and are usually T- and Y-shaped condylar fractures. These fractures are commonly intra-articular and need a CT scan with reconstruction, orthopedic evaluation, and congruous intra-articular reduction and fixation. Coronal shear fractures involve capitellum and trochlea with extension into lateral and medial epicondylar regions. Traction X-rays and CT scan help in planning the surgical fixation of the articular fragments. Olecranon fractures resulted from falls and motor vehicle accidents because of triceps pull. These are splinted and treated with tension band wiring or plating.

Elbow Dislocations

Elbow is the second most commonly dislocated joint in the body resulting in disturbance in the three-point relationship between epicondyles of humerus and olecranon. Posterior dislocation is more common than anterior and divergent dislocations. Associated fractures of both the coronoid and the proximal bones with special attention to the soft tissues and neurovascular structures should be done swiftly and reduction should be attempted under sedation. Postreduction elbow is placed in the sling and X-rays are mandatory to evaluate the reduction, presence of associated fractures, and status of the distal neurovascular structures. Stiffness and heterotrophic ossification are the complications associated with injuries around the elbow joint.

Forearm and Wrist

Forearm injuries are a common presentation in the emergency in both pediatric and adult populations (**Figs. 5A** to **G**).

FIGS. 5A TO G: (A to C) Anteroposterior X-ray showing loss of proximal arc congruity with spilled teacup sign denoting lunate dislocation on lateral and CT scan images; (D and E) X-rays showing K-wire fixation across the reduced lunate; (F and G) Follow-up X-rays.

Courtesy: Dr Ajith Yadav.

Proximal radioulnar, distal radioulnar joints (DRUJ), and interosseous membrane (IOM) provide stability and needed freedom for the bowed radius to rotate on a straight fixed ulna. Among fractures of the forearm, the following fractures require special attention to diagnose the associated fracture-dislocations and associated nerve injuries.

Monteggia fractures: These are proximal ulna fractures with radial dislocation (posterior in adults and anterior in children) at the proximal radiocapitellar joint. Posterior interosseous nerve injury is the most common nerve injury associated with Monteggia fracture,. X-rays showing both elbow and wrist joints are mandatory to diagnose the associated fracture-dislocations. These fractures require operative management and should be splinted and referred for orthopedic consultation.

Galeazzi fractures involve fracture of the middle to distal third radius fracture and with distal radioulnar joint (DRUJ) disruption. X-rays are examined for the shortened radius on AP and dorsal or volar angulated ulna in lateral X-rays. These are the fracture which require surgical management to restore the biomechanics of the forearm.

Essex–Lopresti lesion: It is longitudinal disruption of the interosseous membrane with radial head fracture-dislocations and disruption of the DRUJ. Radial head fracture with widened DRUJ space with positive ulnar variance should raise the suspicion of additional interosseous membrane injury. They need orthopedic consultation for further management.

Wrist involving carpal bones and distal radius is common in *FOOSH injuries.* Distal radius fractures are more common in the older age groups because of osteoporosis and in young because of high-energy trauma and sporting. All the wrist injuries are examined for the possibility of DRUJ, carpal bone fractures (scaphoid), lunate and perilunate dislocations, entrapment syndromes such as carpal tunnel syndrome, and other neurovascular injuries. AP, lateral, and oblique X-ray views are necessary to study the displacement, angulation, articular congruency, and involvement of the carpal bones. Suspected fracture scaphoid, lunate and perilunate dislocations, comminuted distal both bone fractures require CT with reconstruction for the assessment and planning for the surgery. Extraarticular distal radius fracture with minimal angulation can be manipulated and splinted in emergency with the POP slab and with pain control measures. All the splinted forearm and wrist injuries need regular consultations to exclude complications such as compartment syndrome, displacement of the reduced fractures, and nerve injuries.

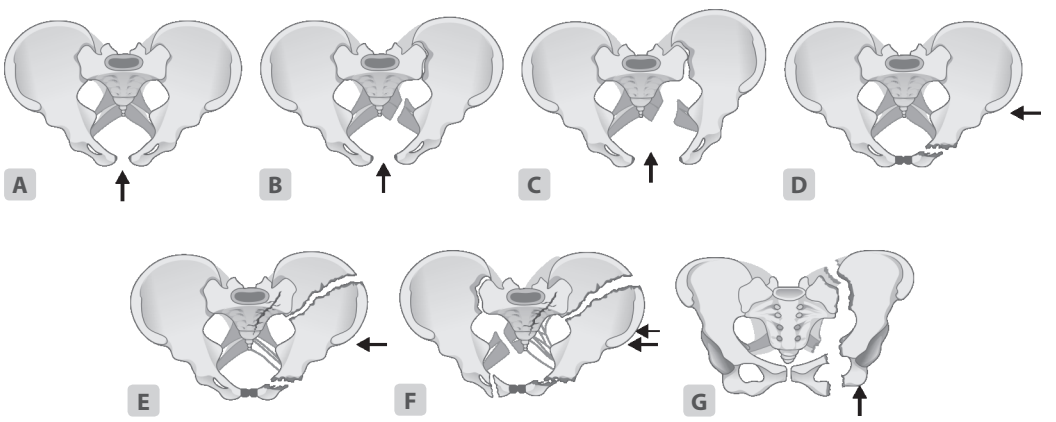
Pelvis

Planning and treatment of the pelvic trauma patient start even before the patient arrives in an emergency. An emergency team with proper arrangements should be in place. Pelvis trauma is very challenging to treat as an immense amount of trauma is needed to cause it and it carries high rates of morbidity and mortality. The pelvis is stabilized anteriorly by symphysis and posteriorly with strong ligaments such as sacrospinous, sacroiliac, sacrotuberous, and iliolumbar connecting the different parts of the pelvis and inferior osseous spine. *Pelvic trauma is classified using the Young and Burgess mechanism* of the injury (**Figs. 6A** to **G**). This is commonly used to predict distant associated injuries, resuscitation needs, and mortality rates.

Tile classification: This is based on biomechanical stability used for surgical planning. Emergency teams should be able to resuscitate, diagnose, and treat the associated injuries. Priority is given to get the hemodynamics corrected and exclude causes of bleeding from the thorax, abdomen, pelvis, and extremities. Simple AP view of the pelvis and inlet and outlet view radiographs give ample information to ascertain the degree of the injury and its effect on the stability of the pelvis. CT scan of the pelvis with reconstruction is needed for detailed study and planning of the surgery.

Stable fractures: These fractures involve only one part of the ring (pubic rami fractures), are minimally displaced (<2.5 cm of diastasis), and are avulsion fractures (ischial tuberosity) and transverse sacral fractures.

Unstable fractures: These involve the pelvic ring in two places with the involvement of the posterior ring. These result from a combination of AP, lateral, vertical, and rotational forces during the impact. Diastasis of >2.5 cm and widening of sacroiliac joint, vertical fractures of the sacrum with asymmetrical sacral foramina, and avulsion fracture of the 5th lumbar transverse process with vertical displacement suggest highly unstable injury. *Open book fractures* are stabilized with large towel sheets around the pelvis at the

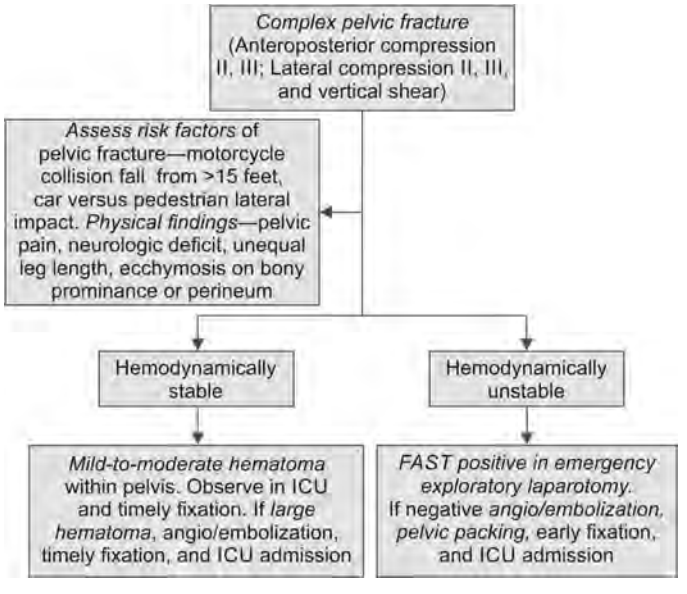


FIGS. 6A TO G: (A) Anteroposterior compression type I; (B) Anteroposterior compression type II; (C) Anteroposterior compression type III; (D) Lateral compression type I; (E) Lateral compression type II; (F) Lateral compression type III; (G) Vertical shear.

level of the greater trochanter to reduce the pelvic volume with caution in lateral compression injuries. *Open pelvic fractures and their associated injuries* are carefully examined. *Tell-tale signs* over the abdomen, flanks, and perineum are inspected for contusions to exclude degloving injuries *(Morel Lavallee syndrome).* The penis should be examined for blood at the meatus. Rectal and vaginal examination is done to rule out communicating fractures. Bilateral hips and lower extremities are checked for fractures and associated soft-tissue injuries with a detailed neurovascular examination. Hemorrhage is a devastating complication of multiple injured patients. Common pelvic sources include venous plexus, cancellous bony surfaces, arterial bleeding (internal iliac vessels), and abdominal injuries. Clinical assessment, labs, judicial usage of the available facilities, diagnostic peritoneal lavage (DPL), focused assessment with sonography in trauma (FAST), CT angiography with embolization or timely laparotomy, and pelvic packing can have detrimental effects in multiple injured patients, especially in nonresponders. Management guidelines for pelvic trauma are summarized in **Flowchart 1**.

Femur and Hip

Femur and hip fractures result from dashboard injuries in high-velocity collisions and from trivial falls in the elderly in association with osteoporosis and metastatic lesions. Acetabulum with proximal femur fractures with dislocations, ipsilateral neck of femur, and shaft of femur fractures need special attention to the neurovascular injuries, loose bodies in case of dislocations and time since injury in case of fracture neck of the femur as these influence the total outcome. All the devices such as traction and braces over the patient should be removed as these are contraindicated in pelvic fractures,



Complex pelvic fracture (Anteroposterior compression II, III; Lateral compression II, III, and vertical shear)
Assess risk factors of pelvic fracture—motorcycle collision fall from >15 feet, car versus pedestrian lateral impact. Physical findings—pelvic pain, neurologic deficit, unequal leg length, ecchymosis on bony prominance or perineum
Hemodynamically stable
Hemodynamically unstable
Mild-to-moderate hematoma within pelvis. Observe in ICU and timely fixation. If large hematoma, angio/embolization, timely fixation, and ICU admission
FAST positive in emergency exploratory laparotomy. If negative angio/embolization, pelvic packing, early fixation, and ICU admission

(FAST: focused assessment with sonography in trauma; ICU: intensive care unit)

FLOWCHART 1: Management guidelines for pelvic trauma (large pelvic hematoma means extend outside the pelvis, resuscitation should be continued in the angiography room, temporary bilateral internal iliac artery embolization is preferred).

fracture-dislocations with ligamentous injuries, and fractures involving open injuries with gross contamination. Physical examination reveals leg length discrepancies, deformities in case of fracture-dislocations. And shortened and externally rotated attitude in case of intertrochanteric and subtrochanteric fractures. Patients can present with hypotension with raised lactate levels, degloving injuries, compartment syndrome, and neurovascular injuries. Trivial falls with refusal to bear weight should raise the doubt of rami fractures or impacted neck fractures and stress fractures are to be screened with CT and MRI. Fracture neck of femur and fracture-dislocations should be reduced at the earliest in an emergency or in operation theater by an orthopedic surgeon as these are associated nerve traction injuries and AVN of a dislocated hip.

Complications such as pulmonary embolism with involvement of more than two long bones, compartment syndrome, heterotrophic ossification, and sciatic nerve injuries (fracture-dislocations) need to be checked and keep the patient informed.

Knee and Leg

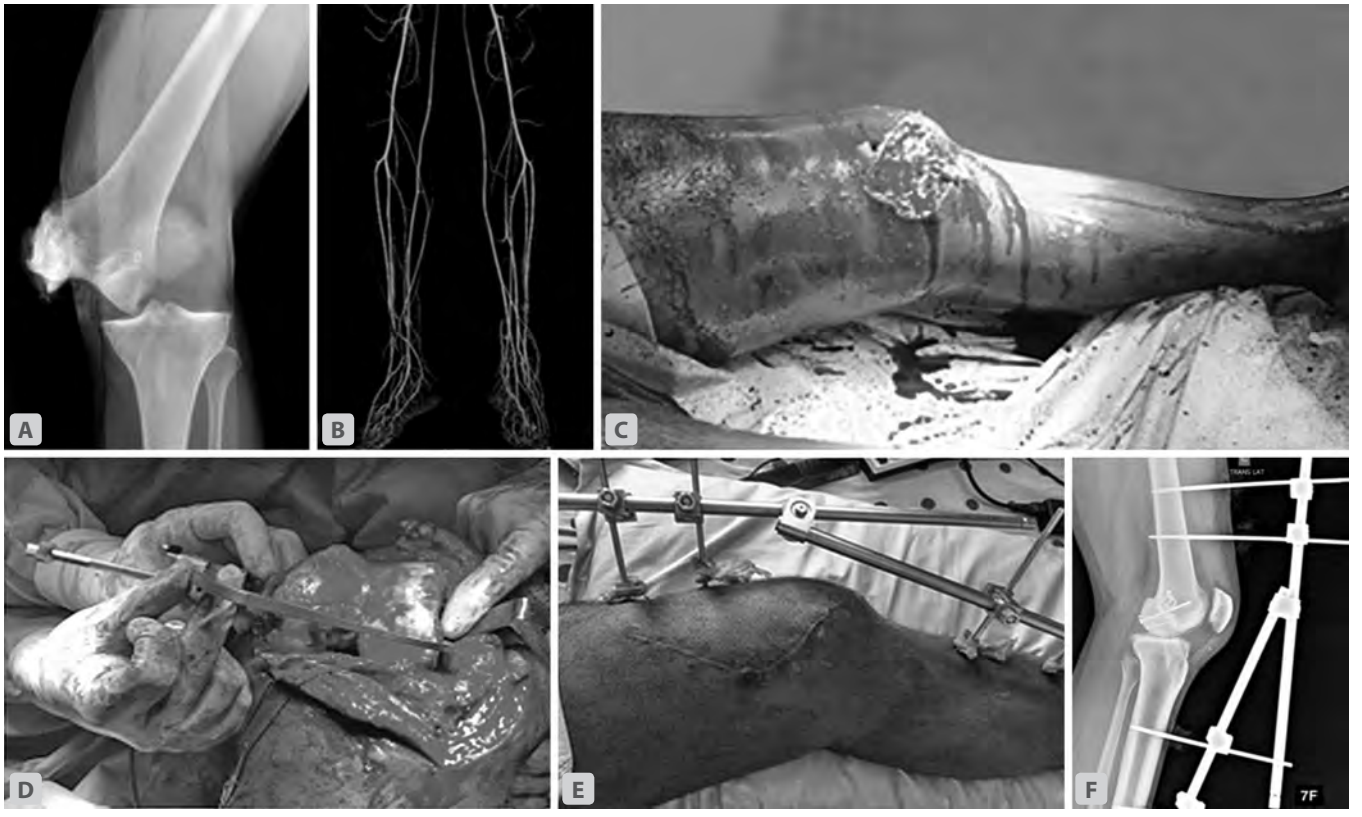
Knee injuries occur in both trivial falls (old age and morbidly obese) and high-energy collisions. They present with pain, instability from ligamentous injury, open injuries with varying degrees of contamination, and involvement of the joint. Understanding the mechanism of injury, examination, and proper diagnostics can minimize the short falls. X-rays of AP and lateral views should be screened for fractures, avulsion injuries [anterior cruciate ligament (ACL) avulsion, Segond fracture], Hoffa's fracture, proximal tibial condyle, fibular head fractures, and osteochondral fragments. *Knee dislocations*. Instability with contusions around the femoral and popliteal areas should raise the suspicion of spontaneously reduced dislocation of the knee (**Figs. 7A** to **F**). Frank dislocations are reduced at the earliest and patients are screened with ankle-brachial index, angiography, and planned for revascularization and fasciotomy procedures.

Open Fractures and Floating Knees

Comminuted open fractures should have X-rays with one joint above and one below with traction to realign the comminuted fracture pattern and help in planning. Floating knees and comminuted fractures associated with ligamentous injuries and other organ injuries are immediately braced and orthopedic, vascular, and plastic surgeons should be informed while the patient is resuscitated with proper wound care, antibiotics and optimized for surgery. Stable fractures and knees with ligamentous injury are stabilized with brace and crepe bandage and referred for orthopedic consultation for complete detailed examination and evaluation with MRI.

Ankle and Foot Injuries

Ankle injuries are regular presentations in the emergency. They range from ankle sprains to frank fracture-dislocations. The majority of the sprains result from supination and external rotation, injuring lateral anterior talofibular and calcaneofibular ligaments tear. Medial-sided injuries are rare because of the stronger deltoid ligament. Syndesmotic sprains



FIGS. 7A TO F: (A) X-ray showing medial knee dislocation. Also note the button over the lateral femoral condyle. (B) Normal lower limb arteriogram. (C and D) Intraoperative picture showing the open wound. The wound extended for fracture fixation and ligament reconstruction. Also, knee spanning external fixation is placed to secure the reduction. (E) Healed wound with ex fix in situ. (F) Post ligamentous reconstruction X-ray lateral view showing ex fix in place. ***(For color version, see plate 43)***

result from injury to anterior tibiofibular, posterior tibiofibular, and inferior transverse ligaments. Physical examination of the syndesmosis reveals pain and tenderness on the squeeze test and crossed leg test with the widening of the medial space on X-rays. All ankle and foot injuries should have AP, lateral, and oblique views of the foot and also AP and lateral views of the ankle. These are screened for medial clear space, medal tibiofibular overlap, associated avulsion fractures of the 5th metatarsal base, talar avulsion fractures, and peroneal tendon avulsions. Most of the ankle sprains are treated *with RICE (rest ice compression and elevation regime)* with a stirrup brace or below-knee POP for 3–6 weeks. Clear instructions to the patient and their attendees should be given to approach an emergency in case of increased swelling, discoloration of the fingers, and pain which is increasing out of proportion.

Ankle Fractures

These are classified according to the *Denis and Weber classification* as they can predict syndesmotic injuries. Fractures involving the fibula at or above the ankle mortise are unstable and require operative management. *Pilon fractures (fracture distal tibia)* are intra-articular extending into the metaphysis and are associated with high-energy trauma with extensive soft-tissue involvement with associated fracture in the pelvis and lumbar spine. These injuries require CT scans with reconstructions and admission for early total care or damage control depending on soft-tissue status, involvement of other fractures, and physiology of the patient. All injuries around the ankle and foot are examined for swelling, soft-tissue status, and involvement of the neurovascular structures and are documented and photographed.

Foot injuries range from simple metatarsal fractures to fracture calcaneum, fracture-dislocation of the talus, and tarsometatarsal junction (*Lisfranc fracture*). Axial load and fall from height are the reasons for injuries. Associated injuries in the knee, hip, and spine are screened and treated. Focused history, understanding the mechanism of injury, detailed examination, adequate investigations, and timely consultation and referral to concerned specialists will help the emergency physician to avoid complications.

SUMMARY

With increasing motor vehicle accidents, sporting activities, and aging population musculoskeletal injury constitutes a major part of emergency departments which demand early recognition, stabilization, care, and referral to the concerned departments for definitive care. Successful optimization and treatment of the patient with musculoskeletal trauma require dedicated teamwork which starts from the site of the accident and by the team of specialists in the hospital.

230
CHAPTER

Vascular Injury

Rohan Shah

INTRODUCTION

"Vascular injury" refers to injury to a blood vessel—an artery or a vein. Trauma to the vascular system can be devastating. These injuries are categorized by the type of trauma that caused them—blunt or penetrating injury. A blunt injury can occur when a blood vessel is crushed or stretched. A penetrating injury can occur when a blood vessel is punctured, torn, or severed. Either type of vascular trauma can cause the blood vessel to clot (thrombosis) and interrupt blood flow to an organ or extremity or cause bleeding which can lead to life-threatening hemorrhage. These injuries can occur in the civilian or military setting. Fortunately, in the civilian setting, it is an uncommon injury that presents to the trauma bay but penetrating vascular injuries are becoming increasingly common in the developed countries. Estimates are that penetrating injuries to the extremities account for 5–15% of traumas. However, overall vascular injuries account for 1% of all traumatic injuries to extremities. Penetrating vascular injury can be classified as extremity, junctional, or noncompressible. Patients with major vascular injuries require multiple team disciplinary physicians. Patients with these injuries may present with obvious clinical deterioration or may progress to a life-threatening condition from a stable clinical condition. Diagnosis can be obvious but at other times subtle and difficult to diagnose. The advancement of endovascular therapies and the advent of computed tomography (CT) with angiography has made progress in the management of such injuries.

ETIOLOGY AND INCIDENCES

Peripheral vascular injuries subdivide by the mechanism of injury and anatomical location.

- *Penetrating wounds*: Stabbing by knives/glass, gunshot, intravenous (IV) drug abuse. Firearm injury constitutes around 50% of penetrating injuries while 30–40% injuries are caused from sharp instruments such as knives or glass.
- *Blunt trauma (adjacent to the major artery)*: Joint displacement, bone fracture. The most common cause of blunt injury is motor vehicle accidents.
- *Invasive procedures*: Arteriography, cardiac catheterization

Arterial injuries are most common, and isolated venous injuries are least common. A venous injury is more likely to occur in combination with an arterial injury. Traumatic vascular injuries are most common in the extremities, which account for 75% of vascular injuries. Of these injuries, lower extremity injuries are slightly more common than upper extremity injuries. In the elderly patient, the preexistence of atherosclerotic disease, particularly peripheral arterial disease, is important in the assessment of the magnitude of injury and consideration for repair.

PATHOPHYSIOLOGY

The mechanism of injury is important in initial assessment. It is helpful to know the type of weapon, angle of entry, and depth of penetration in penetrating injuries but this information is often unknown. To understand the physiology involved in penetrating vascular injuries, it is important to discuss kinetic energy. As kinetic energy is directly proportional to the mass of the object and exponentially proportional to the velocity of the object, vascular injuries by high-velocity weapons are more severe. Similarly, an object that has a greater surface area has the ability to cause more severe vascular injuries but neither the velocity nor object characteristics can independently predict the amount of damage caused; it is more often a combination of both. Vascular anatomy of the great vessels and the particular branch points of the more distal vasculature are important in identifying and potentially preventing morbidity and mortality in the setting of injury. Mechanisms of penetrating vascular injury are: (1) Puncture, (2) laceration, (3) complete transection, (4) partial transection, (5) aneurysm, (6) arteriovenous fistula, and (7) dissection. When the arterial vessel is transected, vascular spasm coupled with low systemic blood pressure appears to promote clotting at the site of injury and to preserve vital organ perfusion better than is the case with ongoing uncontrolled hemorrhage. Ischemia to distal tissues → anaerobic metabolism consumes all substrate → irreversible cell disruption and death → edema → progression of damage.

CLINICAL PRESENTATION

Clinical presentation of penetrating vascular injury is classified into hard and soft signs of injury. This will allow the physician

to decide the best management plan. Signs that are classified as hard signs represent immediate intervention while signs that are classified as soft signs represent diagnostic testing to better elicit the type of injury.

Hard signs:
- External arterial bleeding
- Rapidly expanding hematoma
- Palpable thrill, audible bruit
- Obvious arterial occlusion—pulseless, pallor, paresthesia, pain, paralysis

Soft signs:
- History of arterial bleeding at the scene
- Diminished unilateral distal pulse
- Neurologic deficient
- Proximity of penetrating wound to the major artery
- Small nonpulsatile hematoma
- Abnormal flow–velocity waveform on Doppler ultrasound
- Abnormal ankle-brachial pressure index (<0.9)

DIAGNOSIS

Palpable distal pulse, even if diminished, suggests that the proximal arterial injury is limited. The reasons for diagnostic studies are to:
- Prevent unnecessary operation
- Document the presence of the surgical lesion
- Localize the surgical lesion to plan an operative approach

Arteriography: This is performed by the radiologist using intra-arterial digital subtraction angiography or CT angiography. It is also performed by the surgeon either in the emergency room (ER) or in the operating room.

Duplex scan: It uses real-time B-mode (brightness image) and pulsed-wave Doppler image (flow determination). The physical exam can be augmented by the use of a Doppler ultrasound probe, pulse oximeter, or measurement of the patient's bedside ankle-brachial index. Physical and ultrasonographic exams can be limited in the trauma bay; pulse waves may transmit through fresh thrombus, and vasospasm or vasoconstriction can make healthy vessels difficult to palpate. An ankle-brachial index >0.9 effectively rules out a significant arterial injury causing ischemia and can eliminate the need for further investigation. Oximeter readings of normal pulsatility and saturation can similarly rule out arterial injury in patients with various orthopedic injuries. Ultrasound is efficacious at diagnosing arteriovenous fistulas or pseudoaneurysms and for follow-up of interventions but is limited in the acute phase. CT angiography is a rapid diagnostic tool that can guide endovascular or open surgical intervention in the absence of significant renal dysfunction. The specificity and sensitivity of CT approach catheter-based angiography; however, smaller intimal tears and defects may be missed. Digital subtraction angiography remains the best choice for visualizing smaller vessels and is preferred for hand or foot trauma with evidence of ischemia.

MANAGEMENT

Treatment of peripheral vascular injury is evolving because of endovascular therapies. Guidelines advocate for embolization of injuries to lower extremity branch vessels, including pseudoaneurysms or arteriovenous fistulas, in hemodynamically normal patients without hard signs of vascular injury. The vast majority of stab or gunshot wounds will cause limited soft-tissue damage, muscle ischemia, and/or simple fractures that demand no or very limited wound debridement and bone fixation. The vascular injury can be treated early on without considering the other tissue damage. High-energy penetrating soft-tissue injuries, mostly seen in the military setting, cause frequently major soft-tissue damage with sometimes small and large entry and exit holes, extensive wound contamination, and soft-tissue ischemia as well as compound fractures. These injuries need, in general, early restitution of blood flow of the large damage vessels, e.g., by shunts, while time is consumed by initial wound debridement and necessary fracture stabilization.

The decision for endovascular or open intervention can be difficult and is guided by the patient's clinical status and the anatomy of the injury. When patients are unstable, an open surgery takes precedence; however, in the reasonably stable patient, data are scarce to guide decision-making. As technology changes rapidly, the traditional thinking of mandatory surgical exploration is challenged. Blunt traumatic vascular injuries are largely amenable to endovascular therapy, and some previously high-mortality, penetrating injuries such as those to the visceral vessels can now sometimes be successfully treated with covered stenting. Medical management and observation have been shown to be effective for a range of arterial and venous injuries, particularly subcentimeter intimal flaps or intramural hematomas. Thoracic aortic as well as axillo-subclavian injuries are associated with favorable endovascular outcomes and have the most robust data supporting their use. Patients presenting with penetrating injuries to the chest or severe pelvic injuries may have initial resuscitation augmented by an aortic occlusion balloon.

Initial intervention: Management of penetrating vascular injury in the ER can be classified in hemorrhage control and damage control resuscitation. Adequate vascular access should be obtained immediately.

Hemorrhage control: Direct pressure, tourniquet, or topical hemostatic agent are different modalities. Direct pressure will be the most important step for hemorrhage control. Small vascular clamps are also useful. The use of resuscitative endovascular balloon occlusion of the aorta as an adjunct effectively controls hemorrhage in patients with noncompressible hemorrhage.

Damage control resuscitation: Hemorrhage is controlled without coagulopathies. Permissive hypotension, prevention of coagulation, and balanced component therapy are three principles of damage control resuscitation. Systolic blood pressure (SBP) of 90 mm Hg is acceptable in permissive hypotension strategy with the use of minimal, if any, crystalloid and resuscitation with blood products. Severe traumas will receive a massive transfusion protocol with the use of blood, fresh frozen plasma, and platelets in a 1:1:1 ratio. Simple measures, such as rewarming, prevention of tissue hypoperfusion, and hemorrhage control, can go a long way in reducing the development of the lethal triad of hypothermia, acidosis, and coagulopathy. Administration of tranexamic acid within 3 hours of major trauma has shown reduced mortality.

Definitive management: Definitive treatment is usually surgical or endovascular. Different modalities according to the extent of injuries are available, i.e., bypass graft, ligation,

resection with end-to-end anastomosis, patch angioplasty, lateral arteriorrhaphy or venorrhaphy. Patients with external bleeding or a rapidly expanding hematoma should undergo immediate operation. Exploration of a vascular injury is best performed under general anesthesia in the operating room or, if possible, in a hybrid suite. If signs of acute extremity ischemia are present and there are no other sites of hemorrhage, intravenous heparin should be administered.

COMPLICATIONS

Isolated vascular injury may come with an amputation rate as low as 3%, but penetrating trauma, increased transport times (longer warm ischemia time), and coagulopathy may push the amputation rate up to 33% and higher. Injury to femoral vessels has the highest mortality in comparison to brachial, popliteal vessels because the proximal femoral vessel has the highest flow, no collaterals, may not easily be assessable for bleeding with tourniquet, and may come as multiple vascular injury. Most of the complications for penetrating vascular injuries are delayed and occur after initial evaluation and repair. The ER physician should also consider large vessels injury and nerve injury when evaluating severe trauma.

- Delayed thrombosis (e.g., postoperative anastomoses or shunt placement)
- Intermittent claudication
- Chronic pain (nerve compression/ischemia)
- Edema (venous compression/elevated compartment pressure)
- Aneurysm/Pseudoaneurysm formation

SUMMARY

Penetrating vascular injuries are serious and common presenting complaints in the emergency department (ED). They are associated with significant morbidity and mortality if not addressed early and cared for in the appropriate manner. The management of these patients has improved dramatically by implementing evidence-based clinical practice guidelines. Clinical practice guidelines have proven effective in decreasing mortality from injuries sustained in wartime. The approach to vascular injury in the ED is summarized in **Flowchart 1**.

231 CHAPTER

Management of Orthopedic Injuries

Sandeep Jain

INTRODUCTION

Orthopedic injuries are one of the most common diseases encountered in the emergency department (ED). These are seen in the population of all ages, though modes are different. They can range from subtle soft-tissue injuries to devastating life-threatening injuries. It is important not only to save life and the limb but also to return the patient to a preinjury functional status. Minor fractures or subluxations are one of the commonly missed injuries during trauma management in the ED.

ETIOLOGY OF ORTHOPEDIC INJURIES

Injuries are caused due to transfer of external physical force to the patient's body. Common modes include road traffic injuries, railway accidents, falls, assaults, and sports-related injuries. As injuries can present in various forms, it is important to understand common terms used to describe orthopedic injuries:

- *Fracture*: Disruption in the continuity of a bone, which could be involving one cortex (unicortical) or both the cortices (bicortical).
- *Dislocation*: Disruption of a joint leading to complete loss of contact between articular surfaces.
- S*ubluxation*: Disruption of a joint leading to partial loss of contact between articular surfaces.
- *Sprain*: Stretch or a tear in the ligament of the joint caused due to excessive force.
- *Strain*: Stretch or a tear in the muscle fibers or a tendon resulting from excessive tension or repetitive use.

CLASSIFICATION OF ORTHOPEDIC INJURY

Based on Associated Soft-tissue Injury

Closed fracture: Break in continuity of bone without any breach in the overlying skin.

Open fracture: Bony disruption with a break in overlying skin. These are commonly classified by the Gustilo–Anderson classification (**Table 1**).

Based on Physiology

Common fractures: Fractures caused to healthy bones due to the application of excessive force—direct, bending, axial loading, or twisting force.

Pathologic fractures: Fractures in a diseased bone with the application of minor force, e.g., metastasis, osteoporosis.

Stress fracture: The repetitive force applied to the same area leading to fatigue and weakening of the bone.

Based on Anatomical Site

Epiphyseal fractures: Those involving the epiphyseal plate in children during growing years which can lead to deformities.

Metaphyseal fractures: Those involving areas between epiphysis and diaphysis.

Diaphyseal fractures: Those fractures that involve the shaft.

FRACTURE HEALING

Fracture healing is a complex process involving three phases:

1. *Inflammatory phase (up to 5 days)*: This phase is immediately after fracture, where the blood vessels supply bone break, leading to hematoma formation. This clot formation provides the initial matrix. There is accumulation

TABLE 1: Gustilo–Anderson classification.

Types	*Description*
Type I	Wound 1 cm, minimal contamination or muscle damage
Type II	Wound 1–10 cm, moderate soft-tissue injury
Type IIIa	Wound > 10 cm, gross contamination with extensive soft-tissue damage but adequate soft tissue for coverage
Type IIIb	Significant soft-tissue loss needing flap for coverage
Type IIIc	Associated vascular injury needing repair regardless of the degree of soft-tissue injury

of neutrophils, macrophages, and lymphocytes which removes damaged tissue. Additionally, proinflammatory mediators such as interleukins and cytokines are secreted.
2. *Reparative phase (5–28 days)*: In this phase, release of the vascular endothelial growth factor (VEGF) promotes angiogenesis within the clot. Mesenchymal stem cells recruited to the site differentiate into fibroblasts, chondroblasts, and osteoblasts which help in laying down of fibrocartilaginous matrix—soft callus which holds the two bone ends together. Subsequently, this soft callus undergoes calcification and woven bone is laid down ultimately leading to the formation of hard callus of immature bone.
3. *Remodeling or maturation phase (months to years)*: The hard callus undergoes remodeling due to a continuous process of bone formation by osteoblasts and bone resorption by osteoclasts leading to the replacement of callus into the trabecular bone.

CLINICAL PRESENTATION

Common presentations include pain, swelling, deformity, and loss of function. Most of the times, diagnosis is easy but sometimes it may be missed. The patient may present with minimal or no swelling with mild pain on putting stress over the bone. A good history-taking with a focus on the mechanism of injury helps to diagnose most fractures.

History: The patient usually gives a history of trauma leading to pain and swelling. Knowing the precise mechanism of injury helps in predicting the site of injury, for example, fall on outstretched hand leading to Colles fracture, dashboard injury leading to posterior dislocation of the hip, holding a child from hand causing pulled elbow, fall from height with feet first leading to calcaneal fracture and vertebral fractures, respiratory distress or dysphagia following blow to chest suggestive of sternoclavicular dislocation. Sometimes, the history of direct trauma may not be forthcoming, especially in diseased bones, e.g., stress fracture of the metatarsal bone, fracture neck of the femur in an osteoporotic patient causing sudden loss of movement of the hip. In the ED, a good history-taking for orthopedic injuries is as important as other medical or surgical cases. Special consideration should be given to age, hand dominance, past medical history, current medications, state of the affected bone, and occupational history.

Physical examination: A good physical examination is the cornerstone for the diagnosis of musculoskeletal injuries as it helps to direct further imaging. Adequate analgesia helps in gaining the cooperation of the patient for appropriate examination.

Inspection: Inspect for limb position, swelling or deformity, and overlying skin. An abducted and externally rotated lower limb is suggestive of fracture femur or pelvic fracture; loss of contour of shoulder indicates shoulder dislocation. Skin bruising or laceration may indicate an underlying fracture or a sprain. A pale limb compared to others may indicate neurovascular compromise. If a limb has been splinted before arrival to the ED, it should be opened to assess the condition of the overlying skin. In the presence of a stretched or tented skin, the fracture should be reduced urgently to avoid conversion to open fracture.

Palpation: Deformity or localized tenderness over a bone or a joint suggests fracture or subluxation/dislocation. Palpable crepitus is highly suggestive of an underlying fracture. Pain on weight-bearing could be a sign of occult fracture. Palpation should start in the normal area away from the suspected site of injury. The aim is to localize the point of maximal tenderness. It should be done well beyond the area of tenderness due to the possibility of referred pain. For example, pain in the shoulder could be due to sternoclavicular subluxation, fracture of the clavicle, humerus head fracture, scapula fracture, or rib fracture. It is important to palpate for distal pulsation, sensation, and movement to assess neurovascular status. In delayed presentation, compartments should be palpated to look for compartment syndrome.

Movement: It assesses both active and passive movements. If the patient is able to actively move across the complete range of motion, it effectively rules out any significant injury.

Red Flag Signs

- Cold, pale, immobile limb with absent distal pulsations
- Severe deformity
- Expanding hematoma
- Open fractures
- Fractures associated with hemodynamic instability
- Severe pain not explained by the apparent injury suggests compartment syndrome.

INVESTIGATIONS

Radiographs are commonly ordered for confirmation of diagnosis and treatment planning. X-rays should be ordered based on focused history and physical examination. A good radiograph examines the area of interest in two planes perpendicular to each other. It should include one joint above and below the fracture site. In children, images of the opposite side should be taken for comparison to differentiate fracture from the epiphyseal growth plate. It is important for the emergency physician to understand various changes in alignment of bones to be able to read the radiographs.

The fracture line can be described based on its direction relative to the long axis of the bone (**Fig. 1**):

- *Transverse*: Fracture line runs perpendicular to the bone.
- *Oblique*: Fracture line runs at an angle of 45–60°. It is due to compression and bending forces.
- *Spiral*: Fracture line spirals around the shaft. Usually, torsional forces are involved.
- *Comminuted*: Fracture has more than two fragments.
- *Intra-articular*: Fracture line extends into the articular surface of the bone.
- *Segmental*: Two or more fracture lines running through the bone, together isolating a segment of the bone.
- *Greenstick*: It is an incomplete fracture seen commonly in children. Bone is broken on one side and bent on the other side.

Displacement: It defines the alignment of fracture segments. It is described in terms of the position of the distal fracture segment relative to the proximal fragment. For example, in anterior shoulder dislocation, the head of the humerus lies anterior to the glenoid. Some types of displacement are as follows (**Fig. 2**):

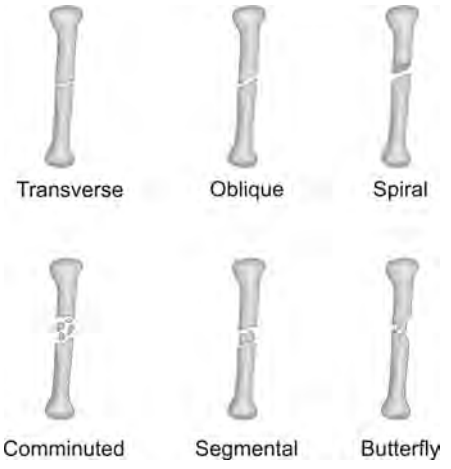

FIG. 1: Types of the fracture line.

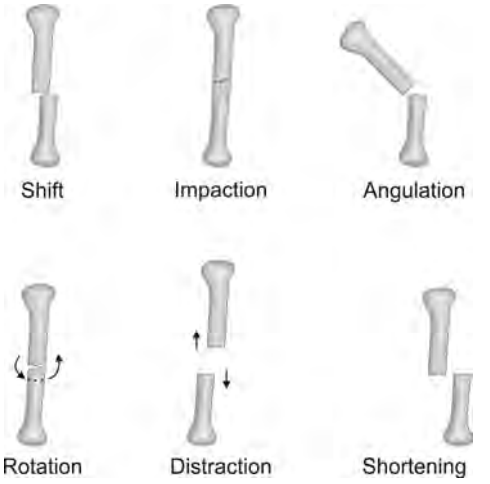

FIG. 2: Types of fracture displacement.

- *Shift*: It is caused by loss of alignment of two fractured segments.
- *Impaction*: Fracture segments are compressed together. These are usually stable fractures and are seen more commonly in cancellous bones.
- *Angulation*: Two fracture segments lie at an angle to each other.
- *Distraction*: It is caused due to excessive traction during reduction leading to the distance between two segments.
- *Rotation*: It causes rotation of the distal fragment along the longitudinal axis of the bone.
- *Shortening*: It happens when the two fractured segments overlap each other leading to reduction in the length of bone.

Some clinical decision rules such as *Ottawa Ankle Rules and Ottawa Knee Rules* are used to reduce exposure to radiographs, but they should be used in conjunction with the history and clinical examination. Ultrasonography is also being used now in ED for confirmation of fractures at the bedside. CT scans delineate fractures and dislocations better than conventional X-rays and provide three-dimensional information. MRI defines soft-tissue injuries better and is easily available.

INITIAL MANAGEMENT

Initial management of any orthopedic emergency is aimed at control of pain and reduction of swelling.

In a prehospital setting or with minor injuries, the RICE method has been proven to provide relief:

- *R*est: Reduction of movement reduces pain and prevents further bleeding.
- *I*ce: Cold compress causes local vasoconstriction and thus reduces swelling.
- *C*ompression: Wrapping the part in elastic compression bandages helps to reduce swelling.
- *E*levation: Raising the affected part at or above the heart level improves venous return and reduces swelling.

Splinting: It stabilizes the fracture segment and prevents further soft-tissue injury. This can be achieved with any locally available hard material such as wood, cardboard, or metal rod. There are commercially available splints such as malleable wire, foam-covered malleable aluminum, and foam-covered cardboard splints which can be easily used for extremity fractures. Various splints are as follows:

FIG. 3: Arm sling.

Figure-of-eight bandage: Historically, this was used for clavicle fractures but has been proven equal to arm sling in efficacy.

Arm sling: It is the most versatile and easy-to-apply splint for upper limb fractures. It supports the shoulder, arm, and forearm (**Fig. 3**).

Shoulder immobilizer: It is a Velcro appliance which keeps the arm in adduction and forearm close to chest and shoulder in internal rotation. It is used for shoulder injuries (**Fig. 4**).

Knee immobilizer: This device extends from the thigh to just above the ankle. It keeps the knee in extension and is used for fracture of the patella, tibial plateau fracture, and meniscal or ligamentous injuries of the knee (**Fig. 5**).

Pain Control

Analgesics: Nonsteroidal anti-inflammatory drugs (NSAIDs) or narcotic analgesia should be used early for pain control. It can be given intravenously or intramuscularly.

FIG. 4: Shoulder immobilizer.

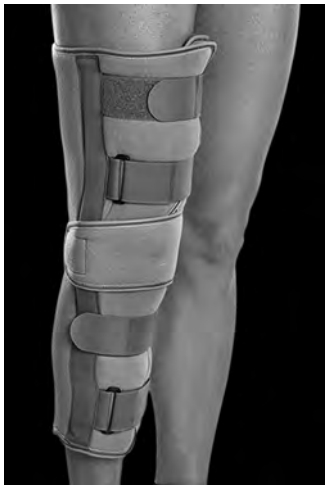

FIG. 5: Knee immobilizer.

Peripheral nerve blocks: Digital nerve blocks and wrist or ankle blocks are used for hand and feet injuries. Femoral or axillary nerve blocks can be used for proximal injuries.

Procedural sedation: Use of sedatives such as propofol, midazolam, or ketamine is needed for painless manipulation of fracture in the ED.

Fracture hematoma blocks: This is used for the reduction of fractures of distal radius or ulna. 10–20 mL of 2% Xylocaine is infiltrated into the hematoma which allows easy and painless reduction.

Fracture Reduction and Immobilization

In ED fracture, immobilization can be done with plaster of Paris or fiberglass bandage which is lightweight and sets early. Splints differ from casts as they are not circumferential and thus allow for subsequent tissue swelling without compromising intracompartmental pressure. Splints allow greater mobility but lesser stability than casts. After adequate analgesia or procedural sedation, an assistant applies longitudinal traction along the axis of the long bone. Any deformity is corrected with manual manipulation and splint applied. Assessment of neurovascular status before and after reduction and splint application should be done in every case.

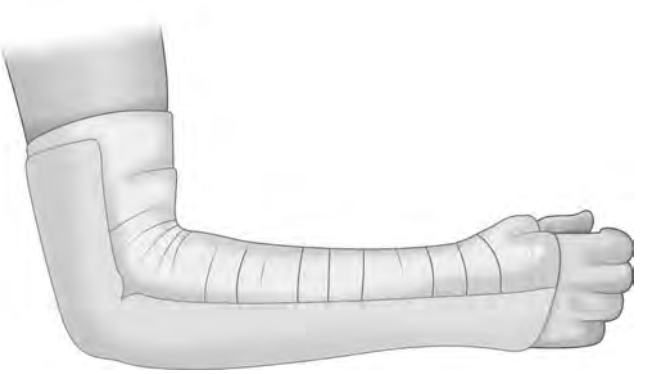

FIG. 6: Long arm gutter splint.

Splinting Technique

The length of the splint should be sufficient to cover one joint above and below. The extremity should be placed in position of function. It should have at least 8–10 layers in the upper limb and 10–12 layers in the lower limb. Measurements are preferably taken before application on the uninjured side. The fractured limb is placed in a stockinette from the proximal to the distal end. A layer of soft cotton is then applied over the limb with extra padding over bony prominences to prevent pressure sores. The splint is soaked in lukewarm water till bubbling stops. Excess water is removed by creasing it in between the index and middle fingers. The splint is then applied and a roller bandage is applied over the splint. It is left to dry till the plaster sets. Some commonly used splints in the ED are as follows:

Long arm gutter splint: It is used for forearm, elbow, and distal humerus fractures. It starts from the head of metacarpals on the ulnar side and extends to the upper arm on its lateral surface (**Fig. 6**).

Thumb spica: It runs from the proximal forearm on the dorsal aspect and involves the thumb (**Fig. 7**).

Long back slab: Starting from the upper thigh on its posterior aspect proximally to the metatarsophalangeal joint distally, it is used for fractures of knee and leg. Plaster is set in a direction where the anterior superior iliac spine, patella, and second toe are in one line with the knee flexed to about 20° (**Fig. 8**).

Thomas splint: This is a traction splint used for fractures of the femur. It is used in conjunction with skin traction. Before applying the splint, the procedure is explained to the patient and provided good analgesia. An appropriate size is selected by measuring the medial length of the uninjured lower extremity and adding 15–20 cm. The circumference of the proximal normal thigh is measured at the groin and 5 cm is added to it. The correct-sided splint has a shortened medial bar and a longer lateral bar with an elevation at its upper end. After selecting the appropriate splint, it is secured with slings along with its length stopping just short of the heel. Skin traction is then applied to the leg leaving room for movement of the foot. Longitudinal traction is then applied to the limb and Thomas splint is slid up till the perineum. The string of skin traction foam is fastened to the distal end (**Fig. 9**).

FIG. 7: Thumb spica.

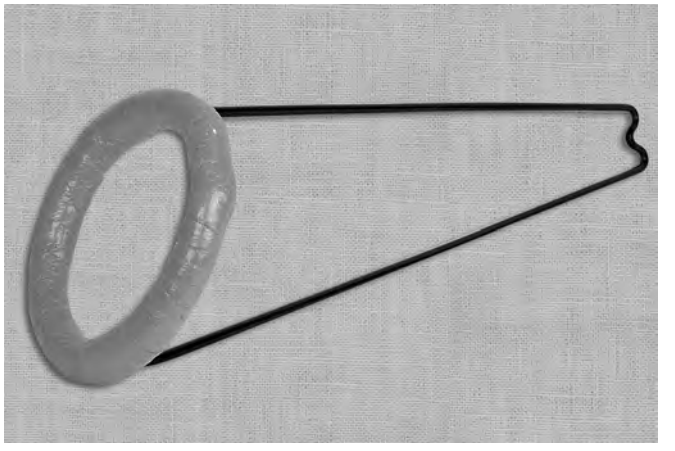

FIG. 9: Thomas splint.

History of trauma
Complaints of pain, swelling, difficulty in weight bearing and/or movement
Local edema, bruising, tenderness, deformity
Hemodynamic instability or impending/manifest neurovascular compromise
Suspeting fracture or dislocation? Confirm with X-ray/CT
Immediate orthopedic consultation
Pain relief with analgesics and nerve blocks reduction and immobilization with splints and cast

FLOWCHART 1: Approach to orthopedic injury in the emergency department.

Open Fractures

Open fractures are known to be distracting injuries. All patients should be managed with the advanced trauma life support (ATLS) principle of airway, breathing, circulation, disability, exposure (ABCDE). After initial stabilization, only fracture is addressed. The most important step in management is to irrigate the wound thoroughly with saline followed by splinting. Wide-spectrum antibiotics should be administered early. The need for tetanus immunization is to be assessed in every case. There should be no attempt to digitally explore any wound in the ED. In bleeding wounds, saline-soaked gauze can be packed in the depth of the wound and direct pressure applied over it with compression dressing. The use of tourniquet is justified in the presence of uncontrolled bleeding.

Sprains

Ligament injuries are classified into first-, second-, and third-degree sprains.

First-degree sprains involve tear of only a few fibers with tenderness and minimal swelling, no functional disability, or abnormal joint movement. Rest with/without immobilization is the treatment.

Second-degree sprains involve partial tear with pain, tenderness, and functional disability with normal joint motion. This needs immobilization.

Third-degree sprain has a complete tear and also shows abnormal joint motion in addition to pain, swelling, tenderness, and functional disability. Best functional outcomes are seen with surgical repair.

SUMMARY

Orthopedic injuries are common presentations in the ED. Pain, swelling, and limitation of movement of the affected part suggest the diagnosis. Initial management includes pain relief and immobilization. Identification of red flag signs warrants immediate orthopedic consult. Diagnosis is confirmed with X-rays/CT scan or MRI. The aim of the treatment is not only to save the life and the limb but also to help the patient return back to the preinjury functional level (**Flowchart 1**).

CHAPTER

Common Orthopedic Procedures

Mihir Dholakia

INTRODUCTION

Many patients who sustain blunt trauma also incur injuries to the musculoskeletal system. These injuries often appear to be dramatic but only infrequently cause immediate threat to life or limb. However, musculoskeletal injuries have the potential to distract team members from more urgent resuscitation priorities. Major musculoskeletal injuries indicate that the body sustained significant forces. For example, a patient with long-bone fractures above and below the diaphragm is at an increased risk for associated internal injuries. Unstable pelvic fractures and open femur fractures can be accompanied by brisk bleeding. Severe crush injuries can cause renal failure. Orthopedic procedures are an integral part of "D"—disability in advanced trauma life support (ATLS) and also in "C"—circulation methods such as splinting, reduction of dislocation, and immobilization in spine boards; cervical collar' application and analgesia blocks are all a part of the procedural protocol in the emergency department.

IMMOBILIZATION OF CERVICAL SPINE AND APPLICATION OF CERVICAL COLLAR

Rigid cervical collars alone do not provide adequate immobilization; they simply aid in supporting the neck and promote a lack of movement. They limit flexion by about 90%. This is used in providing immobilization along with spinal immobilization. The unique purpose of the cervical collar is to protect the cervical spine from compression. The effective cervical collar sits on the chest, posterior thoracic spine and clavicle, and trapezius muscles, where the tissue movement is at a minimum.

A rigid cervical collar:

- Should not be used alone to immobilize
- Must be properly sized for each patient
- Must not inhibit a patient's ability to open the mouth
- Should not obstruct or hinder ventilation in any way.

In some patients, pulling the skull back to the level of the backboard can produce severe hyperextension and padding is needed between the back of the head and the backboard to prevent such hyperextension (**Fig. 1A**). A child's larger sized head relative to the body size, combined with the reduced development of the posterior thoracic muscles, produces hyperflexion of the head when a child is placed on a backboard. Padding beneath the shoulders and torso will (**Figs. 1B** and **C**) prevent this hyperflexion.

Application of a cervical collar: In a two-person technique, one maintains inline immobilization of head and cervical spine and the collar is slid underneath the neck and the strap turned over to the front up to the chin. Secured with straps, the size is approximately from the angle of jaw up to the superior

FIGS. 1A TO C: (A) Placing the folded towel or padding under the head in adult aligns the airway structure. (B) When the child is supine without padding the shoulder, the neck can flex and airway obstruction can occur. (C) By placing the folded towel or padding, all airway structures are properly aligned.

border of trapezius in finger-breadths. Small, medium, large, and extra-large collars should be available. The techniques for cervical collar application are shown in **Figures 2A** to **F**.

HELMET REMOVAL

The two-person technique is used for immobilization of the cervical spine. The next step is the expansion of the helmet and opening of the visor shield. Pull the helmet backward while tilting it forward to clean the nasal bridge and apply gentle extension to clear the occipital protuberance. The method of helmet removal is shown in **Figures 3A** and **B**.

IMMOBILIZATION OF TRAUMA PATIENT AND LOG ROLL

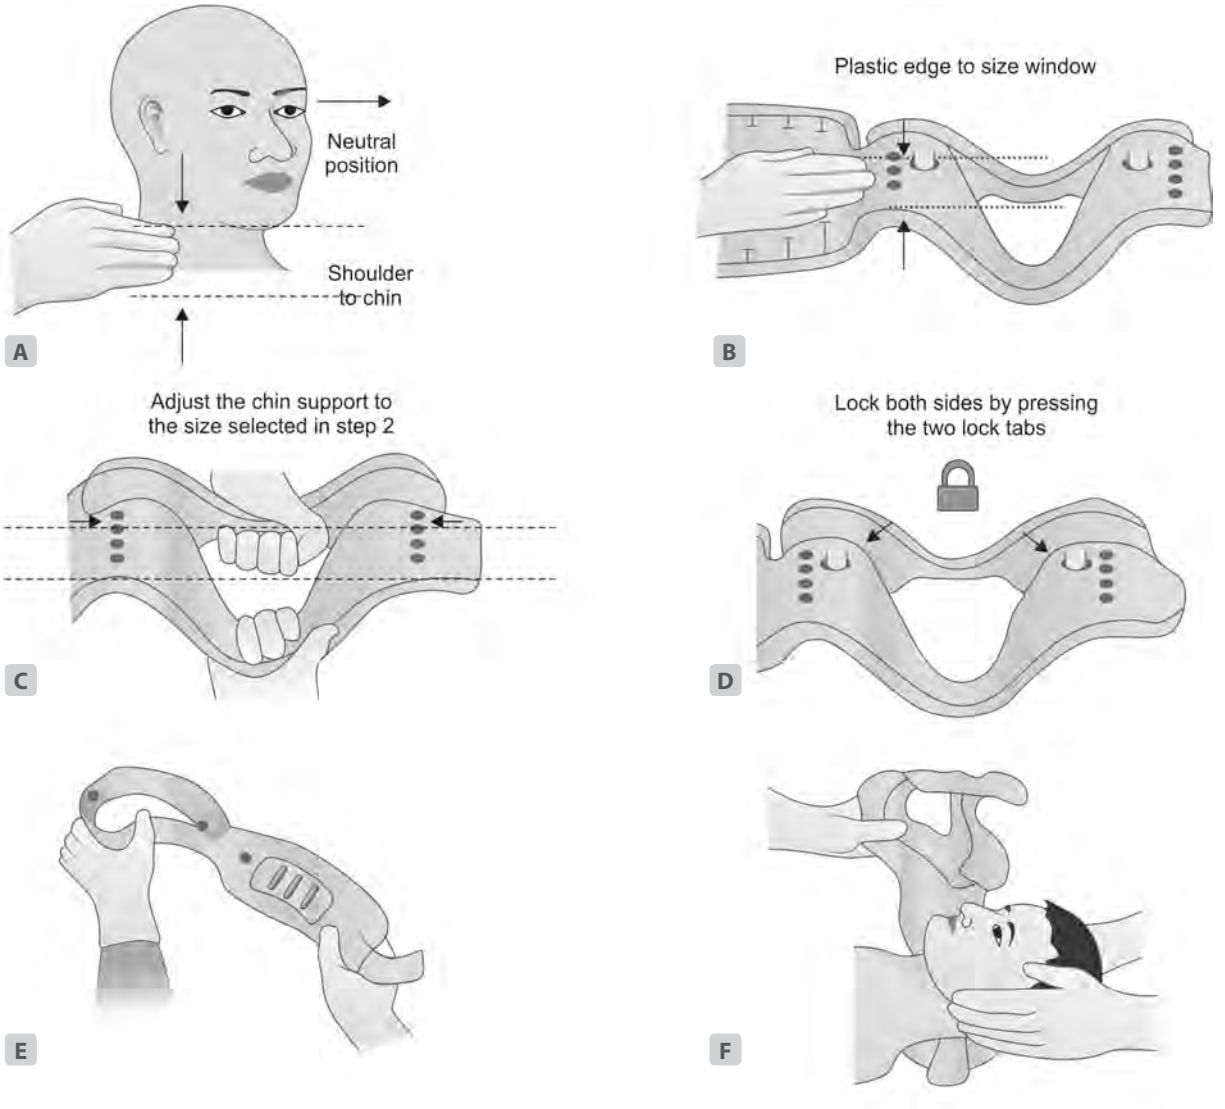
The principle is to fully immobilize a supine patient to a long backboard while maintaining the head and neck in a neutral position and minimizing the risk of additional injuries. The patient's head and neck are moved into a neutral inline position when a cervical collar is applied. The spine board is slid beneath the back by an acceptable method. Maintaining manual stabilization, the upper torso is secured to the backboard. Padding is inserted under the patient's head as needed to maintain a neutral inline position. The final step in immobilizing the patient to the board is secure the lower extremities.

Log roll: This is a four-person technique. One person maintains inline immobilization of the cervical spine—a taller person near the shoulder and a shorter person near the leg. One holds the shoulder and pelvis and the other crosses the arm over the pelvis and knees and then simultaneously at a count from the head end, turn the patient like a log. The fourth person examines the back for any steps or injury marks and clears any debris over the couch. The method for spine board immobilization and log roll is shown in **Figures 4A** and **B**.

FRACTURE MANAGEMENT: TRACTION

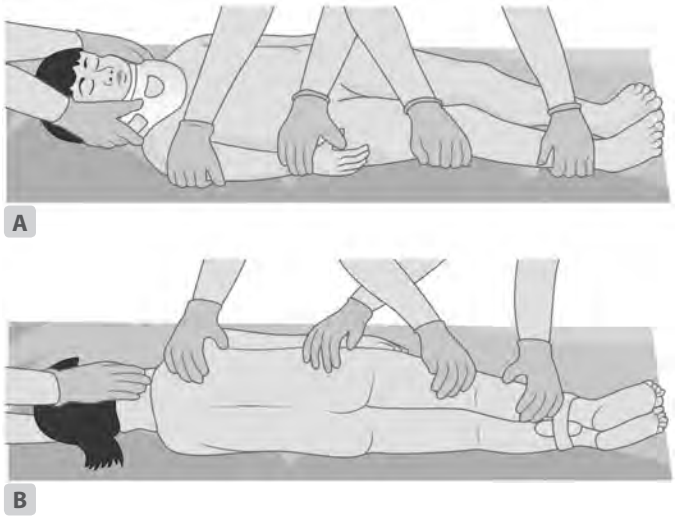
Skin Traction

Skin traction is used for elderly neck femur fractures and distal femur fractures as a temporary method of immobilization till



FIGS. 2A TO F: Techniques for cervical collar application.

FIGS. 3A AND B: Gently slip the helmet about halfway and then stop and remove the helmet and stabilize the cervical spine. Apply a cervical collar and secure the patient to a long backboard. Pad is needed to prevent neck flexion or extension.



FIGS. 4A AND B: Log-roll technique.

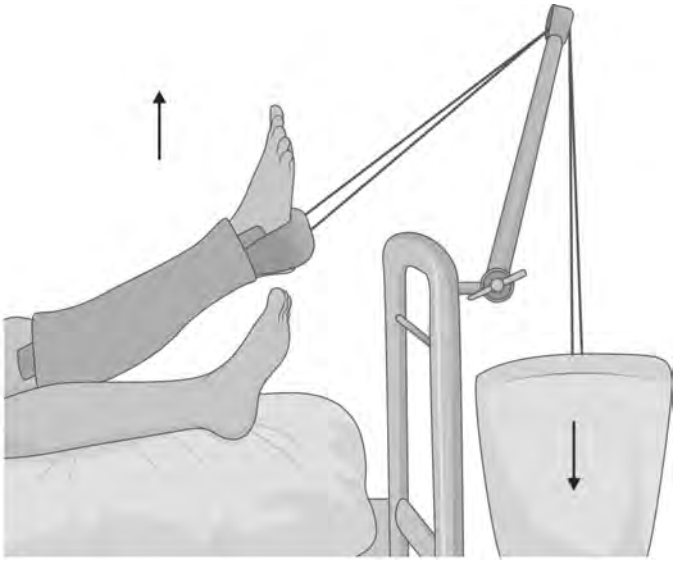


FIG. 5: Skin traction.

a definitive method such as fixation is done (**Fig. 5**). Adhesive or nonadhesive skin traction is used for reduction in pain with weights up to 2–3 kg of mild traction. Always check the distal neurovascular status after application of traction. *Disadvantages* include that it cannot give more traction, can lead to maceration of the skin, not a very effective method of traction, and can lead to neuropraxia with tight bandages.

Skeletal Traction

Skeletal traction is used for effective traction for a longer period of time, through a Steinmann pin or Dirham (threaded) pin (**Fig. 6**). With this method, more weights (up to 7–10 kg) can be attached if the bone quality is good. In osteoporotic patients, the Dirham pin is used to engage the thread in bone. *Main disadvantages* are that this is an invasive method through the bone, can lead to bone infection and superficial skin infection, and can get loose in very weak bones. *Types of skeletal traction* are described depending on the area it is applied, e.g., skull traction, distal humerus traction, proximal hip screw traction, distal femur traction, proximal tibia traction, distal tibial skeletal traction, and calcaneal pin traction.

Materials and equipment required for skeletal traction are sterile tray and drape (including T-handle/hammer), sterile gloves of proper size, 1% or 2% plain lignocaine, power drill, povidone–iodine solution, traction stirrup for leg, strings to hang weights, and blunt plugs to cover the sharp ends of the pin.

Principles of skeletal traction: Skeletal traction is used prior to definitive surgical treatment to improve pain and prevent shortening from soft-tissue contraction. It is inserted from the side that has neurovascular structures at most risk (e.g., in distal tibia—medial to lateral; proximal tibia—lateral to medial; calcaneal—medial to lateral). Apply local anesthetic up to the periosteum to prevent pain while insertion. Always check the pulse and distal neural status after pin insertion and application of traction.

Distal Tibial Pin

Place the patient in the supine position and place a bolster under the knee for flexion at 60–90°. Palpate the adductor

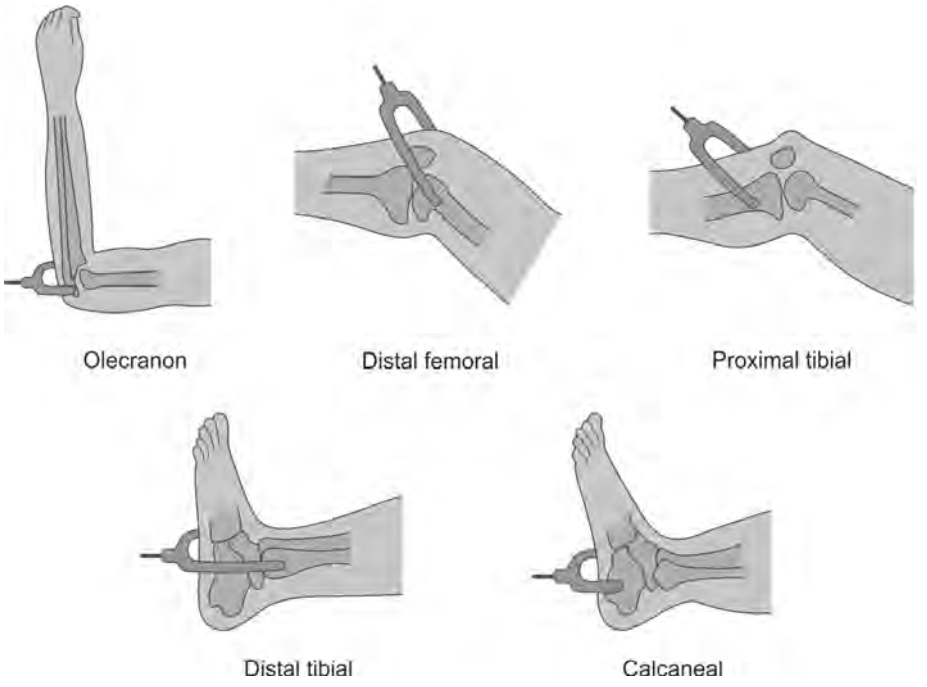

FIG. 6: Site of skeletal traction.

FIG. 7: Skull traction.

tubercle onto the anterior one third of the femur. Infiltrate the skin with anesthetics up to the periosteum. The pin is inserted bi-cortically from the medial to the lateral side.

Proximal Tibial Pin

Place the patient in the supine position. Rotate the knee into neutral or slight internal rotation. Infiltrate the skin and periosteum with an anesthetic agent, 1.5 cm below and posterior to the tibial tuberosity which is the site of insertion, from lateral-to-medial to avoid injury to the common peroneal nerve.

Skull Traction

It is used to apply a traction force to the skull to enable the reduction of dislocated facets. It is used in cervical spine injury (**Fig. 7**) and as a preoperative method for surgical stabilization of the cervical spine. *Cervical traction*: Cervical tongs are indicated in serious cervical injuries, conservative management of cervical fracture, and dislocation. Common complications are bleeding, sore on the skull, sepsis, and worsening neurological status. Cervical tongs may be contraindicated in children, local sepsis, and skull fracture.

FRACTURE MANAGEMENT: SPLINTING AND CASTING

Acute trauma to bone leads to fracture. Acute pain and deformity prompt the patient to visit the emergency department. Pain management, reduction of the fracture, and immobilization are the key elements in the management. In the majority of cases, a plain X-ray is sufficient but sometimes computed tomography (CT)/magnetic resonance imaging (MRI) is required. Reduction of fracture and splinting are recommended to reduce pain and blood loss and to prevent injury to the surrounding structure. Reduction of fracture is helpful in re-establishing anatomic alignment and promote fracture healing. Local hematoma works as a medium for callus formation, which then bridges together the two ends of the fractured bone. Common fractures and their splinting procedures are given in **Table 1**. Padding in a cast or splint is a balance between protecting the soft tissues and maintaining immobilization. Underpadding will result in skin breakdown or frank ulceration. Overpadding may lead to a loosen cast or splint and poor support.

Key features: Proximal and distal extents should have a cuff of soft roll of three to four layers with a minimum of two layers of padding spanning the two extremes. Bony prominences require attention and adequate padding to avoid crumping of padding and compromising soft tissues and neurovascular structures. Do not bend the joint once the material has been applied. Never use water above room temperature when working with fiberglass splints or casts, as heating may cause thermal injury. Delay means unusable and half-hardened plaster. Plaster slabs should be 8 layers thick for the upper extremity and 10 layers thick for the lower extremity. If an assistant is helping, hold the injured extremity underneath the stockinette and padding and never use fingers to stabilize the limb; always use the palm.

TABLE 1: Common orthopedic injury and splinting procedure in the emergency department.

Injury	*Orthopedic procedure/spilt*
Distal phalanx fracture of the hand	Finger protector splint
Boxer's fracture	Ulnar gutter splint
Metacarpal fracture	Radial or ulnar gutter splint
Scaphoid fracture	Thumb spica splint
Carpal fracture	Dorsal splint of the forearm
Radius and ulna fracture	Sugar tong splint
Elbow dislocation	Posterior long arm (elbow) splint
Supracondylar fracture of the humerus	Posterior long arm (elbow) splint
Proximal humerus fracture	Coaptation splint, sling, and swathe
Shoulder dislocation	Shoulder immobilizer or sling and swathe
Metatarsal fracture	Posterior short leg (posterior ankle) splint
Ankle sprain	Posterior short leg (posterior ankle) splint
Ankle dislocation	Trilaminar ankle splint
Distal tibia/fibula fracture	Trilaminar ankle splint
Knee dislocation	Knee immobilizer or a knee splint
Patellar dislocation	Knee immobilizer or a knee splint

Emergency physician should be aware of the complications of the splinting and casting as described below:

- *Pressure sores*: Avoid by providing sufficient padding over bony prominences and areas of stress.
- *Inadequate immobilization*: Overpadding allows for more mobility.
- *Joint stiffness of adjacent joints*: Avoid by immobilizing only the necessary joints and splinting the affected joint in a functional position.
- *Compartment syndrome*: Avoid by not wrapping the extremity too tightly with the elastic bandage as well as performing a postsplinting functional and neurovascular assessment.

TYPES OF SPLINTS

Crammer Wire/Malleable Splints

Crammer wire is made up of malleable aluminum wires attached to a strong but flexible aluminum rod. The splint can bend easily at any angle (**Fig. 8**). The main purpose is to keep the upper or lower limb in the desired position and preoperative management of the patient for immobilization. Available in various sizes ranging from the width of 2″, 4″, 5″, and 6″ and length of 12″, 18″, and 24″, malleable splints are temporary methods for upper and lower limb immobilization. They are reusable, waterproof, and lightweight. They are made up of malleable aluminum with foam and padding, fastens in place with tape or strap, and can be cut by household scissors (**Fig. 9**).

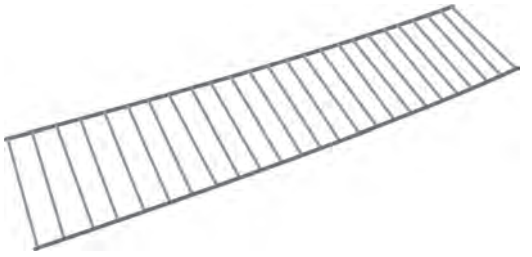

FIG. 8: Crammer wire.

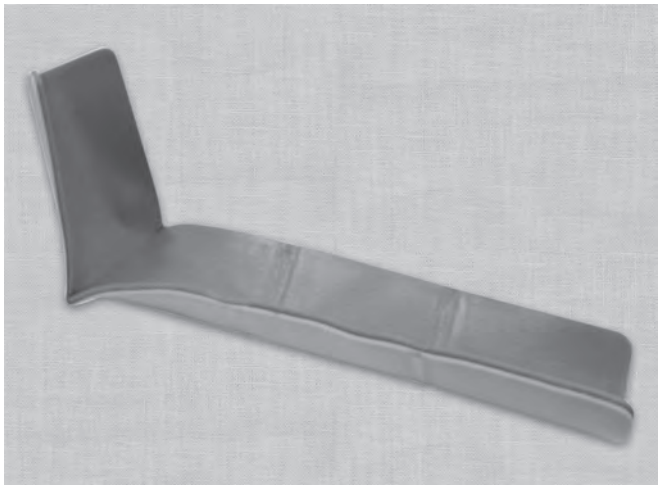

FIG. 9: Malleable splint.

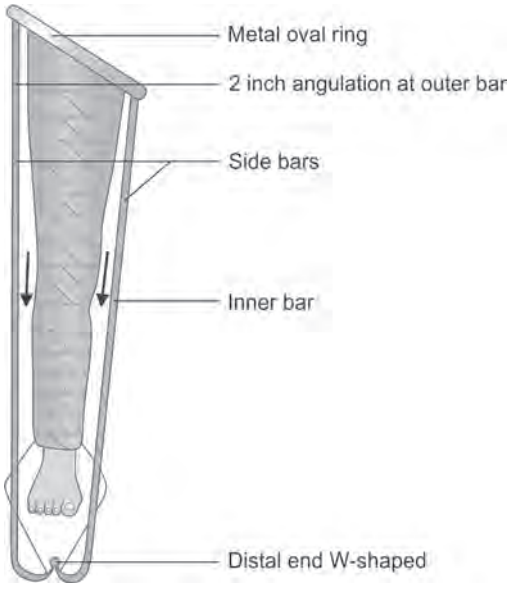

FIG. 10: Thomas splint.

Thomas Splint

It was devised by Hugh Owen Thomas. It was initially used for tuberculosis of knee, but now commonly used for immobilization of hip and thigh injuries (**Fig. 10**). A modified Thomas splint adapted the original splint to include a traction screw and footplate and limb support. It is used for subtrochanteric fractures and shaft femur fractures. It is easy to use and apply whilst maintaining maximum patient comfort.

It reduces morbidity in 80% of cases. There is a ring at the proximal end of the groin (45° placed angle), which goes about 6 inches beyond the footplate. It can be used with traction and is different for left and right sides. Look for neurovascular deficit once traction is given after the application of splint. It is helpful in transporting the patient.

Inflatable Splints

These are a good first-aid and temporary measure for immobilization of fractures which surround the extremity including the digits. Few disadvantages are involved such as risk of occlusion of blood vessels which becomes greater in the extremity in which blood supply is already compromised. Unwanted high pressure may lead to necrosis of digits. It is a plastic piece of first aid equipment that is premade in the shape of a limb (**Fig. 11**).

Coaptation Splint

Used over the shoulder, this is a splint to immobilize the shoulder and humerus (**Figs. 12A** and **B**). This splint is most commonly used for mid-shaft humerus fractures, which have a tendency to fall into varus angulation. By incorporating a valgus bump at the level of the medial elbow, angulation can be avoided.

Essential materials: Materials used are 6″ stockinette, three rolls of 6″ soft roll, three rolls of 6″ plaster; three 6″ compressive bandages, and 2″ tape, It is a large sling. *Steps*: Measure the length of the plaster slab from the axilla of the affected arm, distal around elbow flexed to 90°, then up the lateral arm, and then over the top of the shoulder to the level of the middle one third clavicle. Create a cast eight layers thick. Place soft padding layer over the skin side and over the backside of the cast. Cut one stockinette down the middle, approximately 24″, long enough to pull the remaining stockinette up to the axilla. Wet the slab and place it on the padding of the extremity. Wrap the remaining slab down around the elbow flexed to 90°. Starting at the elbow, wrap the splint using a 6″ compressive bandage, moving proximally. Secure the compressive bandage with 2″ tape. Once dried, place the arm in a large sling to keep the elbow flexed to 90°. The stockinette may be left tied about the neck or cut off for patient comfort.

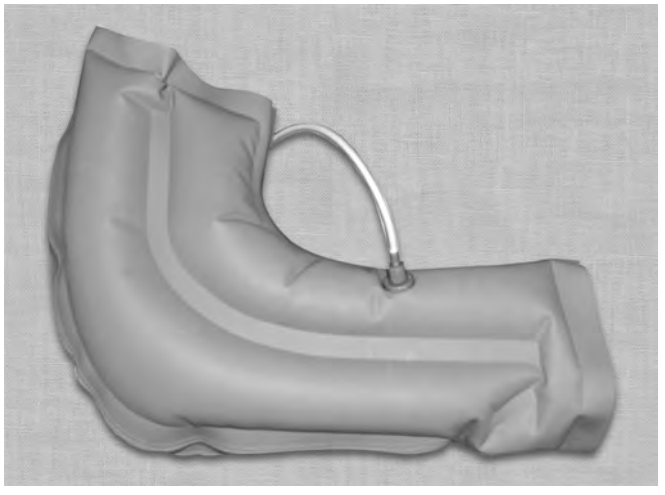

FIG. 11: Inflatable splint.

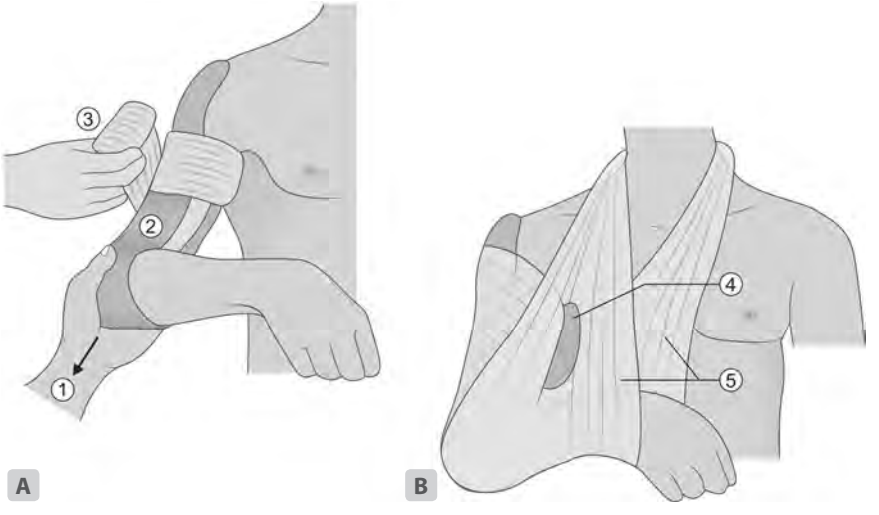
UPPER EXTREMITIES IMMOBILIZATION

Long-arm Splint and Long-arm Cast

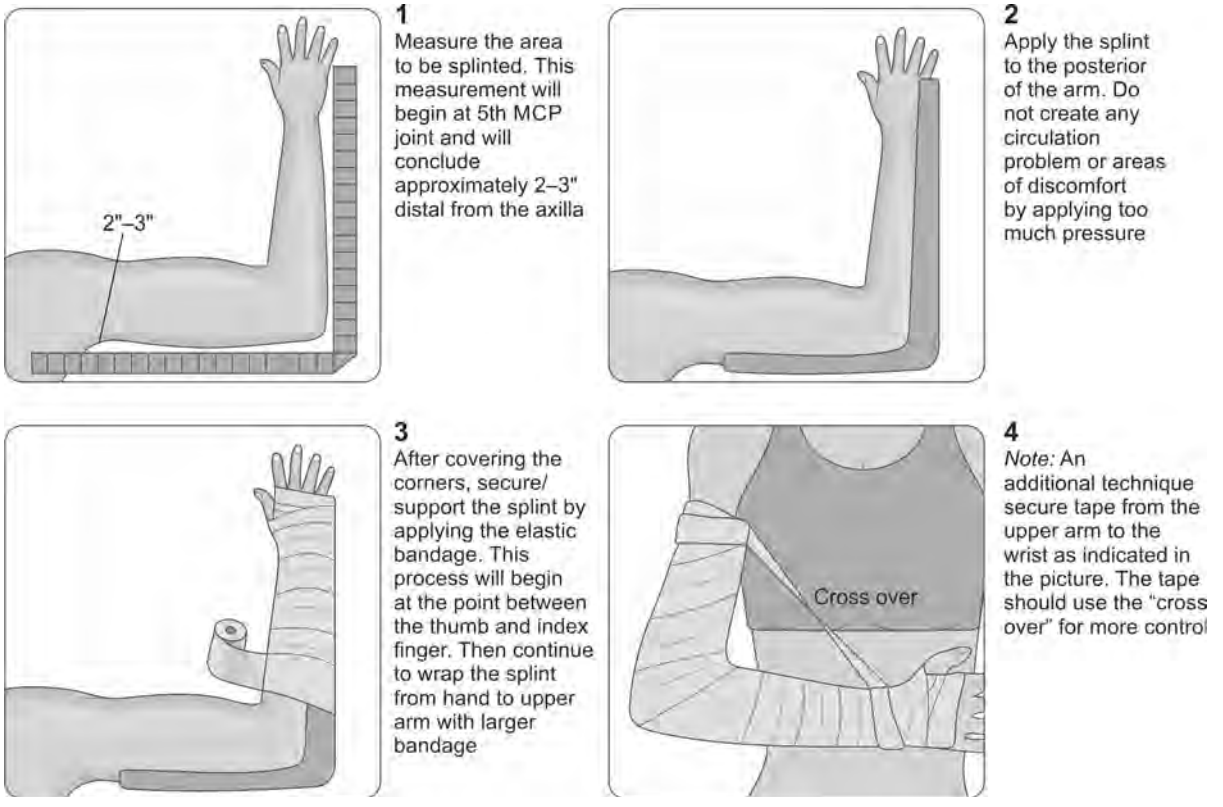
These are used to immobilize distal humerus and elbow and upper forearm (**Fig. 13**).

Materials: Materials used are three rolls of 4″ soft roll, three rolls of 4″ plaster, one roll of 4″ and 6″ compressive bandage, 2″ tape, and a sling.

Steps: Measure plaster slab from the wrist to the axilla with the elbow at the desired degree of flexion. Apply soft roll from wrist proximally to axilla. Place three to four layers of extra padding over the posterior elbow. Wet plaster and put it over the medial or posterior aspect of the elbow from the wrist to the mid-forearm to just above the mid-humerus (at the deltoid insertion). *Long-arm cast:* It has similar steps to long-arm splint except that it has to stay clear of the thenar eminence and metacarpophalangeal (MCP) joints to allow full hand range of motion (ROM). Extend the cast from the wrist to three finger-breadths distal to the axilla using 4″ fiberglass.



FIGS. 12A AND B: Coaptation splint.



1
Measure the area to be splinted. This measurement will begin at 5th MCP joint and will conclude approximately 2–3" distal from the axilla
2"–3"
2
Apply the splint to the posterior of the arm. Do not create any circulation problem or areas of discomfort by applying too much pressure
3
After covering the corners, secure/ support the splint by applying the elastic bandage. This process will begin at the point between the thumb and index finger. Then continue to wrap the splint from hand to upper arm with larger bandage
4
Note: An additional technique secure tape from the upper arm to the wrist as indicated in the picture. The tape should use the "cross over" for more control
Cross over

(MCP: metacarpophalangeal)

FIG. 13: Long-arm splint.

Advance 50% with each wrap. Ensure no further flexion of the elbow during casting due to the risk of compression of neurovascular structures by excess material. Cut thumbhole in distal stockinette and pull back over thumb and hand to create padded cuff at the mid-palmer crease. Fold proximal stockinette over to create padded cuff over the proximal upper arm. Use fiberglass to apply the final cast layer. Stay 1 cm from the edge of the cuff to protect soft tissues. For any edema or compartment syndrome, the cast should be bivalve using a cast saw.

Sugar Tong Splints

Along-forearm splints is used to immobilize the elbow and wrist. The slab is cut for thenar eminence and stops at the mid-palmar crease. It is used for immobilizing Colles fracture. The reduction of a wrist is held by a long, curved mold applied to the splint, maintaining radial height and restoring volar tilt.

Ulnar Gutter Splint

A forearm splint is used to immobilize the wrist and fourth/fifth digits.

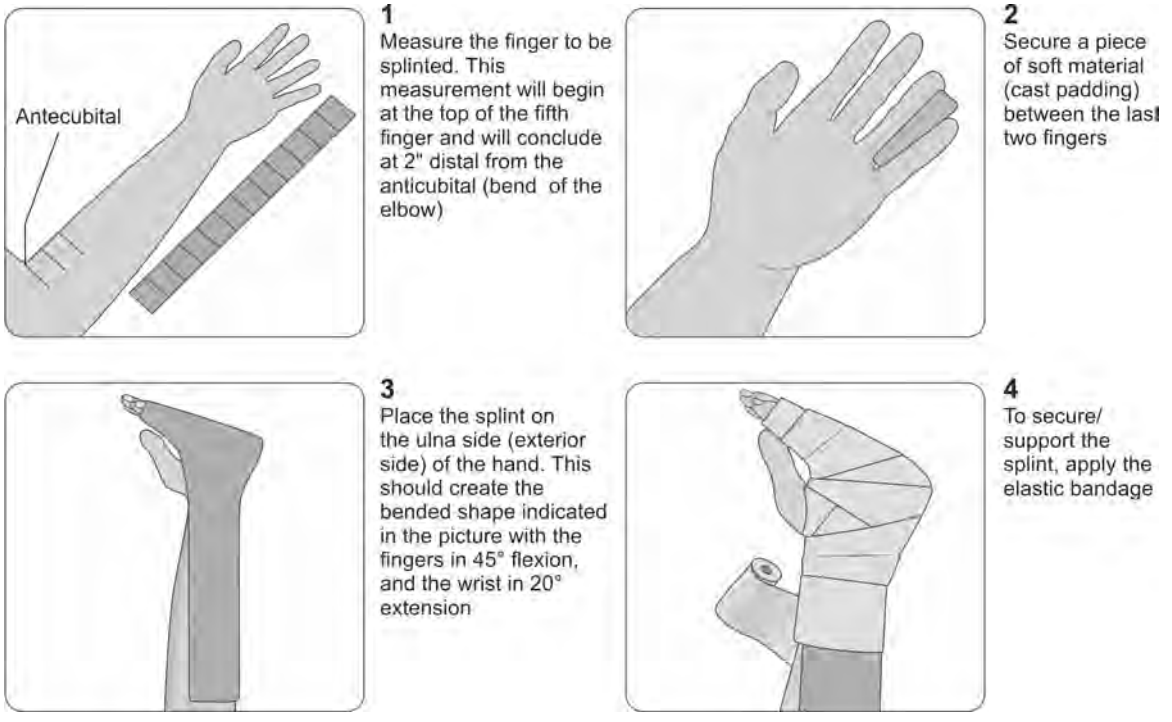
Materials: Materials used are one 3″ soft roll, one 4″ soft roll, two rolls of 4″ plaster, one roll of compressive bandage, and 2″ tape. *Method*: Measure the length of plaster from the distal tips of fourth/fifth fingers along the medial aspect of the forearm to two finger-breadths distal of the level of antecubital fossa. Wet the plaster and lay along the length of the forearm, placing a 2″ distal slab over the volar and dorsal fourth/fifth digits. Stay medial, to keep from impinging on the third digit. Flex fourth/fifth digits to 90° at the MCP joint, adjusting plaster so that it does not wrinkle on the volar aspect. The volar slab will now be longer than the flexed digit and can be trimmed back with shears. Wrap the splint from the distal to the proximal with 3″ compressive dressing (**Fig. 14**).

Short-arm Cast

It is a durable immobilization of the forearm and wrist (**Fig. 15**). The materials needed are forearm length 4″ stockinette, one soft roll of 3″, and one roll of 3″ fiberglass. *Method*: Roll 4″ stockinette onto the affected arm from the level of the proximal interphalangeal (PIP) joints to several inches above the elbow. Roll on the soft roll from the mid-palmer space crease to two finger-breadths distal to the antecubital fossa. Wet 3″ fiberglass and wrap once around the wrist and move distally, up to the mid-palmer crease. When passing through the first webspace, use shear to cut transversely through 90% of material to avoid impingement in webspace. Stay clear of the thenar eminence and MCP joints to allow full hand ROM.

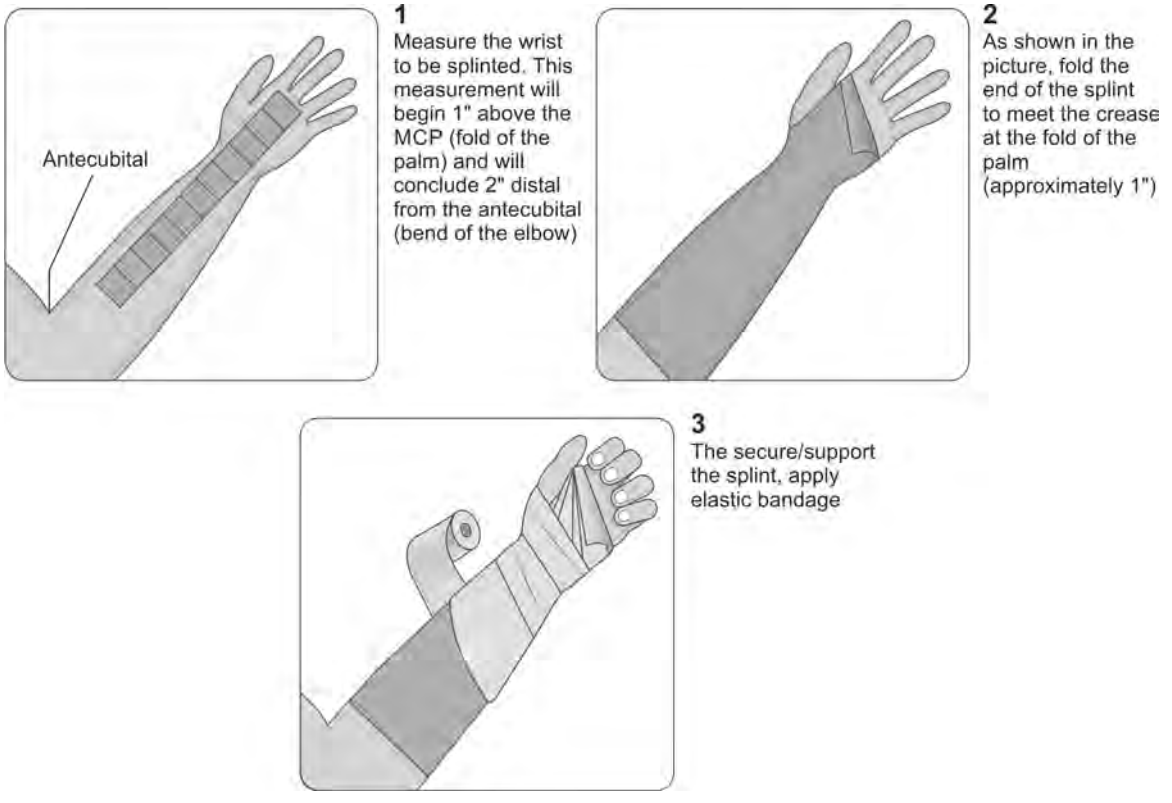
Thumb Spica Cast

It immobilizes the first MCP and wrist joints (**Fig. 16**). The materials used are a forearm length of 6″ of one stockinette, 4″ of one stockinette, one roll of 3″ soft roll, two rolls of 2″ fiberglass, and one roll of 3″ fiberglass. *Method*: Roll a 4″ stockinette onto the affected arm from the level of PIP joints to several inches above the elbow. Cut a longitudinal slit halfway along 1″ stockinette and pull it over the thumb so that the slit is oriented toward the first web space, causing the material to



Antecubital
1
Measure the finger to be splinted. This measurement will begin at the top of the fifth finger and will conclude at 2" distal from the anticubital (bend of the elbow)
2
Secure a piece of soft material (cast padding) between the last two fingers
3
Place the splint on the ulna side (exterior side) of the hand. This should create the bended shape indicated in the picture with the fingers in 45° flexion, and the wrist in 20° extension
4
To secure/ support the splint, apply the elastic bandage

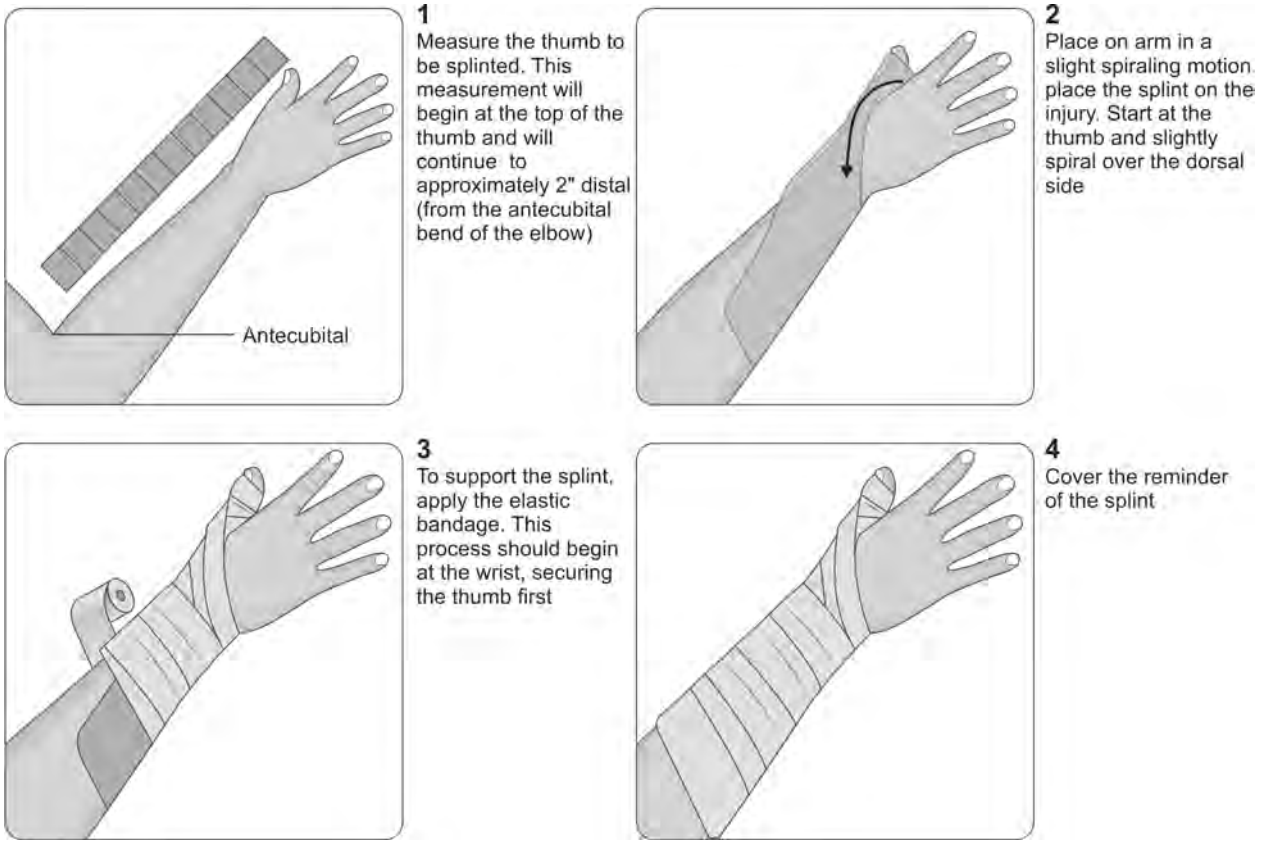
FIG. 14: Ulnar gutter splint.



Antecubital
1
Measure the wrist to be splinted. This measurement will begin 1" above the MCP (fold of the palm) and will conclude 2" distal from the antecubital (bend of the elbow)
2
As shown in the picture, fold the end of the splint to meet the crease at the fold of the palm (approximately 1")
3
The secure/support the splint, apply elastic bandage

FIG. 15: Short-arm splint.

flare over the lateral base of the thumb. Then roll on, on the soft roll from the mid-palmer crease to two finger-breadths distal to antecubital fossa. Extend up the thumb to the level of the nail plate. Wrap around the wrist and move distally up to the mid-palmer crease. When passing through the webspace, ensure that impingement is avoided in webspace. To achieve the desired positioning, give the patient a wrapped roll of fiberglass or plaster bandage to gently squeeze, putting the thumb in "soda can position" (abduction, extension, and pronation).



1
Measure the thumb to be splinted. This measurement will begin at the top of the thumb and will continue to approximately 2" distal (from the antecubital bend of the elbow)
Antecubital
2
Place on arm in a slight spiraling motion place the splint on the injury. Start at the thumb and slightly spiral over the dorsal side
3
To support the splint, apply the elastic bandage. This process should begin at the wrist, securing the thumb first
4
Cover the reminder of the splint

FIG. 16: Thumb spica splint.

Metacarpal Mitt Splint

It is a functional hand splint for metacarpal fractures. Measure plaster slab from the base of the thumb, running over the dorsum of the hand, around the ulnar aspect, and back along the volar surface to the base of the thumb.

LOWER EXTREMITIES IMMOBILIZATION

Long-leg Splinting

It is a long, well-padded splint for immobilization of both the knee and the ankle (**Fig. 17**). Measure a 6″ long plaster slab from two to three finger-breadths distal to buttock crease, along the posterior leg with the knee flexed 10–15° to toes. Measure two long 4″ plaster slabs from the proximal thigh to the plaster heel. Have an assistant hold foot elevated with the ankle in the neutral position and knee flexed to 10–15°. Create a plantar footpad extending from the toes to the above ankle using five layers of 6″ soft roll. Extend the splint as approximal as possible without impingement on the inner groin or buttock to maximize immobilization.

Long-leg Cast

Its principles are similar to those of long-leg splint. It is used for temporary immobilization. Extend the cast as proximal as possible without impinging on the inner groin or buttock to maximize immobilization. The knee should be flexed 10–15° to allow the leg to swing through and to take tension off gastrocnemius for fracture reduction.

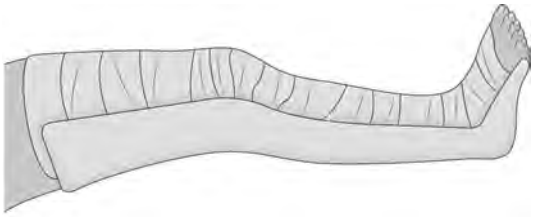


FIG. 17: Long-leg splinting.

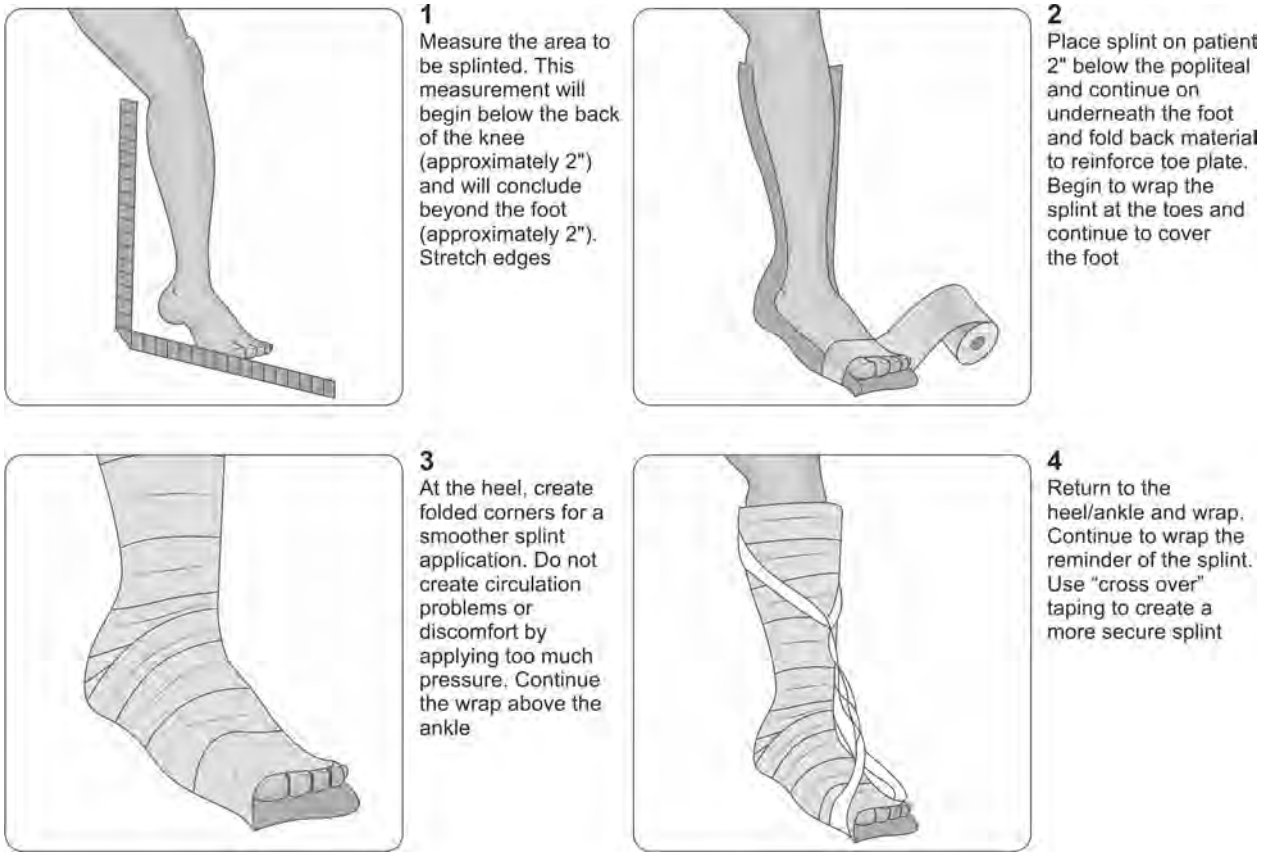
Robert Jones Bulky Dressing

It implies relative knee immobilization using a soft roll. It can be used for any joint though. Wrap knee with soft roll beginning over the proximal tibia and extending to the distal femur. Continue wrapping back and forth over the knee until dressing is five to six layers thick. The dressing may be over wrapped with a compression bandage secured with tape or used in conjunction with a knee immobilizer.

Short-leg Cast

Its principles are similar to a short-leg splint (**Fig. 18**). Wrap foot and ankle, starting distal to the metatarsophalangeal (MTP) joint, and extend proximally using a soft roll to the level of the tibial tubercle. In addition to reduction mold, a triangular anterior tibial mold and midfoot arch mold should be considered for a well-fitting cast.



1
Measure the area to be splinted. This measurement will begin below the back of the knee (approximately 2") and will conclude beyond the foot (approximately 2"). Stretch edges
2
Place splint on patient 2" below the popliteal and continue on underneath the foot and fold back material to reinforce toe plate. Begin to wrap the splint at the toes and continue to cover the foot
3
At the heel, create folded corners for a smoother splint application. Do not create circulation problems or discomfort by applying too much pressure. Continue the wrap above the ankle
4
Return to the heel/ankle and wrap. Continue to wrap the reminder of the splint. Use "cross over" taping to create a more secure splint

FIG. 18: Short-leg splint (posterior ankle splint).

JOINTS DISLOCATION: REDUCTION TECHNIQUES

Shoulder Dislocation

Anterior dislocation: It is the most common form of shoulder dislocation. It is possible to reduce the dislocation with the help of analgesics, intra-articular block or sedation. Lay the patient supine with the affected arm adducted to the side with the elbow extended. Stand on the affected side and grip hand, pilling axial traction and making small, short vertical oscillations, as though shaking his/her hand. Gradually, abduct the arm with continued oscillations at 90°, externally rotate the shoulder, and continue abduction and oscillations. The reduction should occur by 120° of abduction. *Traction-countertraction*: Place a sheet around the patient's torso, into the affected axilla. Lay the patient supine and give a sheet to the assistant or tie it to the far bed rail. Abduct the affected arm 45° and pull axial and inferior traction. Continue attempts of gentle external rotations, and lateral traction with maintained axial traction can aid the humeral head in clearing the glenoid (**Fig. 19**).

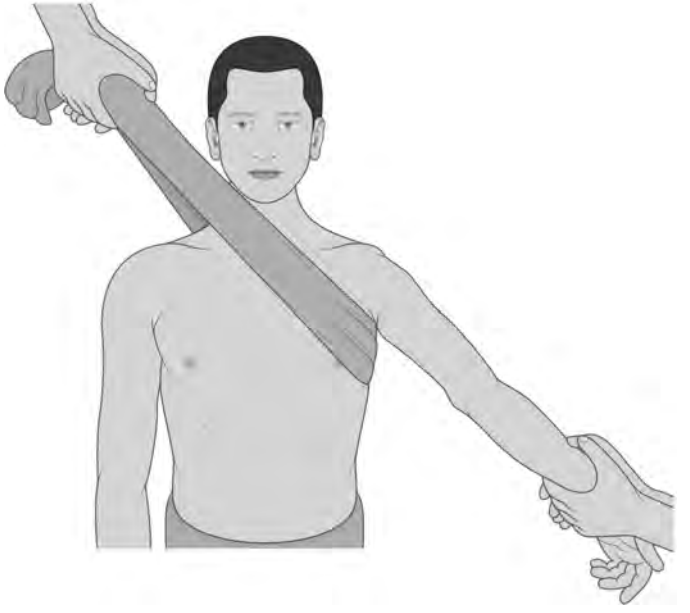


FIG. 19: Traction-countertraction method.

Stimson's-gradual relocation using hang: Use broad pieces of stockinette or tape to secure weight, being careful of possible skin damage Do not consider in patients with fragile skin. Allow gentle traction for 15–20 minutes. It may increase weight up to 10 lbs (**Fig. 20**).

Posterior dislocation: It is much less common. Classic mechanisms include seizure and electric shock. It is difficult without proper sedation. Forward and flex the affected arm to 90°. Abduct across the midline and internally rotate. The assistant on the contralateral side of the body can pull axial traction while the humeral head is milked anteriorly. External rotation can sometimes help with final reduction.

Inferior dislocation: Also called *luxatio erecta humeri*, it presents as arm fixed in abduction. *Traction-countertraction*: Pull axial and superior traction and gradually decrease abduction to

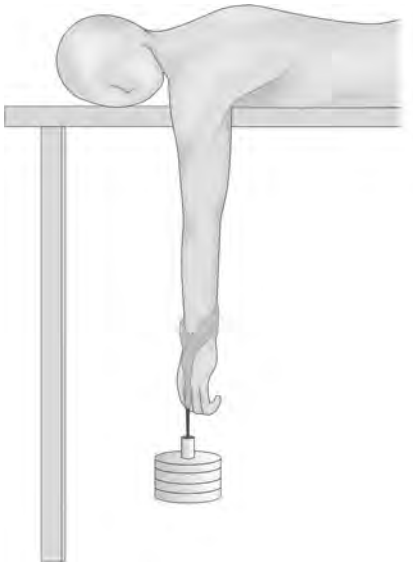

FIG. 20: Patient lies prone with the weight attached to the wrist.

reduce the humeral head. *Two-step technique*: The basic is to convert an inferior dislocation into an anterior dislocation. This procedure is initiated by standing at patient's head, push downward directed force on lateral mid-shaft humerus, while pulling upwards on the medial elbow.

Elbow Dislocation

Most dislocations are posterolateral and can be either simple or complex (with associated fractures). To reduce the dislocation, the patient can be positioned either prone or supine on the bed (**Fig. 21**).

Metacarpophalangeal Dislocation

Similar to interphalangeal joint dislocations, most MCP dislocations are dorsal. The reduction should avoid axial traction or hyperextension and can be achieved with joint flexion. Wrist flexion also helps by relieving tension on flexor tendons.

Interphalangeal Dislocation

Proximal interphalangeal dorsal dislocations: Simple—middle phalanx in contact with the condyle of the proximal phalanx. *Complex*—shortening with bayoneting of the middle phalanx over the proximal phalanx. The reduction should not involve axial traction, especially in complex dislocations, or the volar plate may become interposed in joint. Reduce with hyperextension of the middle phalanx with palmar-directed force. Once dislocation is reduced, buddy tape is applied to bordering digit. Associated intra-articular middle phalanx fracture requires a dorsal extension blocking splint. *PIP volar dislocations*: Reduce with dorsal-directed force and axial traction. Immobilize in extension due to central slip injury. *Rotatory PIP dislocations*: To relax lateral bands, flex MCP and PIP to 90° and pull axial traction. This may require an open reduction. *Dorsal distal interphalangeal dislocations*: These are similar to PIP dorsal dislocations. There is a risk of volar plate interposition with axial traction. Attempt reduction with hyperextension and palmar-directed force.

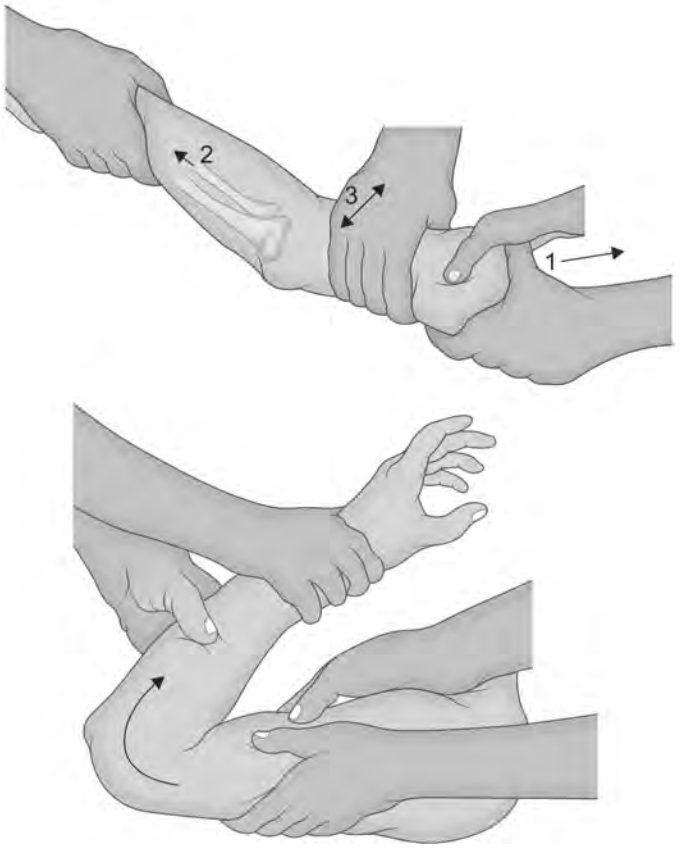

FIG. 21: Reduction of elbow dislocation.

Hip Dislocation

It requires adequate sedation to allow for reduction without further injury to the articular surface. Hip dislocations can be either anterior or posterior, with the posterior being the most common. Reduction maneuvers, regardless of dislocation, involve axial traction in line of deformity. A maximum of two attempts should be done. An assistant can help by placing his/her hands on the pelvis and providing countertraction. *Allis maneuver:* It involves axial traction with gradual hip flexion combined with alternating internal and external rotation. Always look for ipsilateral knee injuries for intra-articular fracture (**Fig. 22**).

Knee Dislocation

Anterior dislocation is most common and posterior. Neurovascular injuries are common, and an evaluation of distal pulses on presentation may decide the line of management. Obtain an ankle-brachial index even in cases where pulses are present before and after reduction. Any medial/lateral translation or rotation of the tibia should be corrected as axial traction is applied. Splint knee at 20–30° after reduction and obtain X-ray.

Ankle Fracture-dislocation

Ankle fracture-dislocation is a result of rotational injuries. The classification of injury is helpful in management and to do a neurovascular examination. Any concern for soft tissues requires urgent reduction prior to imaging. Fractures often result in lateral displacement of the talus under the

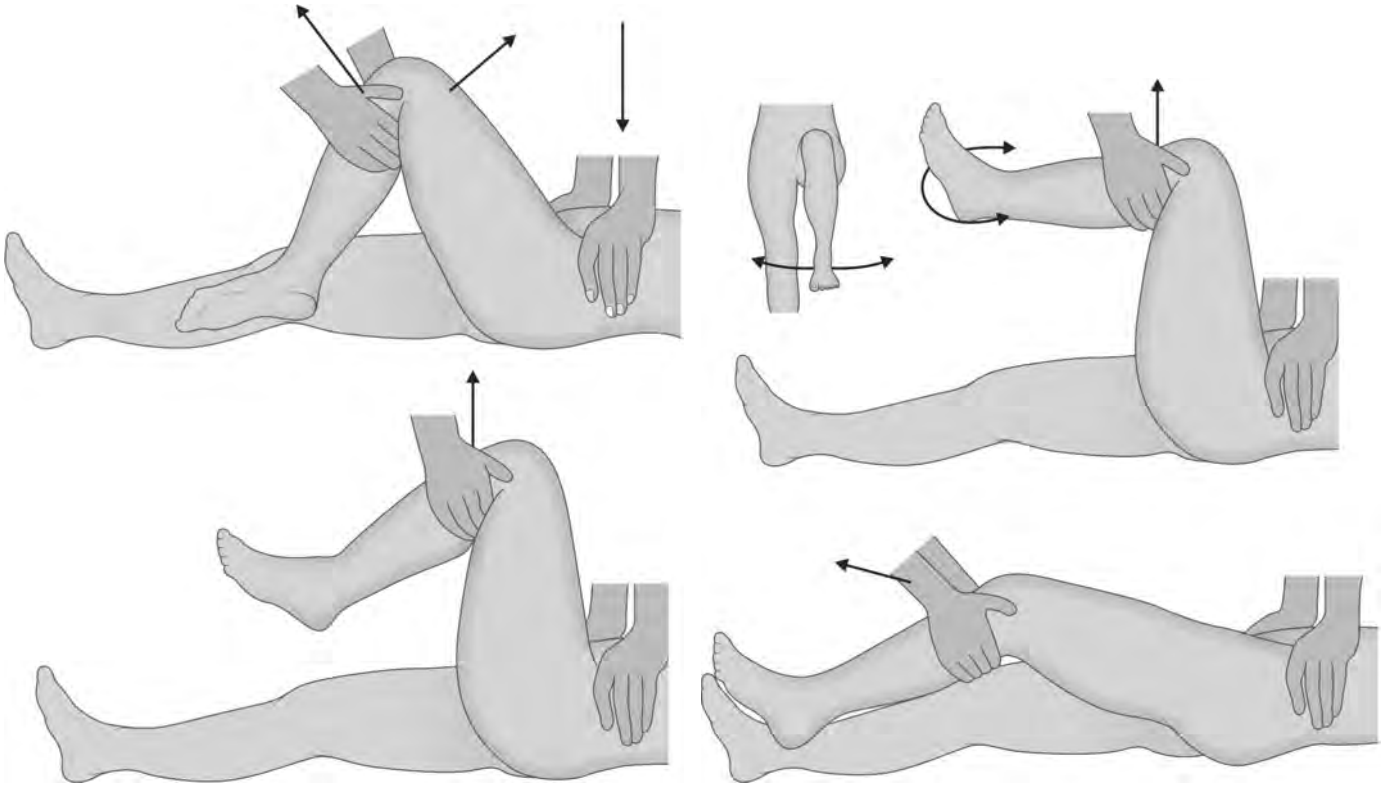

FIG. 22: Allis maneuver.

tibial plafond due to external rotation through the ankle at the time of injury. Dislocations associated with fractures of the tibial posterior malleolus can be very unstable with posterior displacement of the talus. Reduction requires plantar flexion of the foot, axial traction, and anterior translation of the hindfoot. Unstable ankle fracture-dislocations can be best treated by reduction, immediately followed by X-ray to confirm reduction prior to splinting.

Subtalar Dislocation

The talus often remains in place, with medial or lateral displacement of the calcaneus and dislocation of both the talonavicular and the talocalcaneal joints. Early reduction of closed dislocations is important to relieve pressure on the skin and soft tissues. It may require adequate sedation with knee flexion and ankle plantar flexion. Medial dislocations are fixed in supination. Lateral dislocations are fixed in pronation. Obtain CT scan in all cases of high-energy trauma.

LOCAL ANESTHESIA AND BLOCKS

Fast-acting local anesthesia in the emergency department is most commonly lidocaine, either 1% or 2% solutions, no >4 mL/kg. The maximum effect of lidocaine is reached in 5 minutes and will last for 30–60 minutes. Infiltrate lidocaine around the entire periphery of the wound to work in a systematic fashion. It can be used intradermally/intramuscularly about the periphery of lacerations or infected sites.

Hematoma Block

It is used for extra-articular fractures. Analgesia can be provided by infiltrating lidocaine directly into the fracture hematoma, allowing the local anesthesia to diffuse about the injury. Fractures presenting more than 1 day after injury are less amenable to the block due to clotting of hematoma. Review the X-ray and palpate the fracture site and consider local neurovascular structures to determine a path for injection. Sterile preparation is initiated and a use 22G needle to inject the fracture site. Prior to infiltrating, attempt to aspirate hematoma. A small amount of blood aspirate is essential for infiltration by a local anesthetic. If the bone is encountered, infiltrate small amounts of lidocaine below the periosteum. Progress the needle along with bone until it falls into fracture defect and hematoma.

Intra-articular Blocks

Infiltration into a joint is an effective method to provide analgesia for a reduction of dislocation or intra-articular fracture.

Median Nerve Block

First identify the palmaris longus and flexor carpi radialis brevis and longus tendons by having the patient oppose the thumb and fifth digit and flexion of wrist. The injection site will be between these two tendons at the level of the proximal palmar crease. If the patient lacks the palmaris longus tendon, the site will be ulnar to the flexor carpi radialis tendon. Insert a 24G needle at the insertion site and advance approximately 1 cm at which depth the needle will pop through the flexor retinaculum.

Radial Nerve Block

The superficial sensory branch of the radial nerve divides at the level of the radial styloid to provide sensation over the dorsum of the hand. To give a subcutaneous injection of

2 cc of 1% lidocaine over the lateral aspect of radial styloid, lateral to the palpable radial artery, redirect the needle toward the Lister's tubercle to continue infiltrating lidocaine subcutaneously, creating a large wheal that extends to the middle of the dorsum of the wrist.

Ulnar Nerve Block

The injection site is at the distal ulna, proximal to the wrist and dorsal to the flexor carpi ulnaris tendon.

Digital Block

Each digit is innervated by a pair of dorsal digital nerves. By infiltrating local anesthetic proximal to the digit, these four nerves may be blocked. *Subcutaneous technique*: Using a 26G needle, create a subcutaneous wheal of 1% lidocaine just proximal to webspace or radial side of the digit. Advance needle volery and infiltrate to block the volar digital nerve. Aspirate to ensure that the needle is not in the digital vessel. Ensure that infiltration does not contain epinephrine to cause vascular spasm and necrosis. *Transmetacarpal technique*: This targets the common volar digital nerve between the metacarpal heads prior to its division. Insert the needle through the volar skin at the distal palmar crease on the radial side of the metacarpal neck of the digit. Circumferential ring blocks should not be used as an increase in pressure can result in necrosis.

ARTHROCENTESIS

Indications of arthrocentesis:

- Evaluate monoarticular arthritis.
- Evaluate traumatic arthritis.
- Identify the cause of an effusion.
- Rule out joint infection.
- Diagnose inflammatory versus noninflammatory disorders.
- Identify intra-articular pathology (fracture or intra-articular disruption).
- Identify crystal-induced arthritis.
- Use as a pain control measure (by aspiration of fluid).
- Inject therapeutic agents.

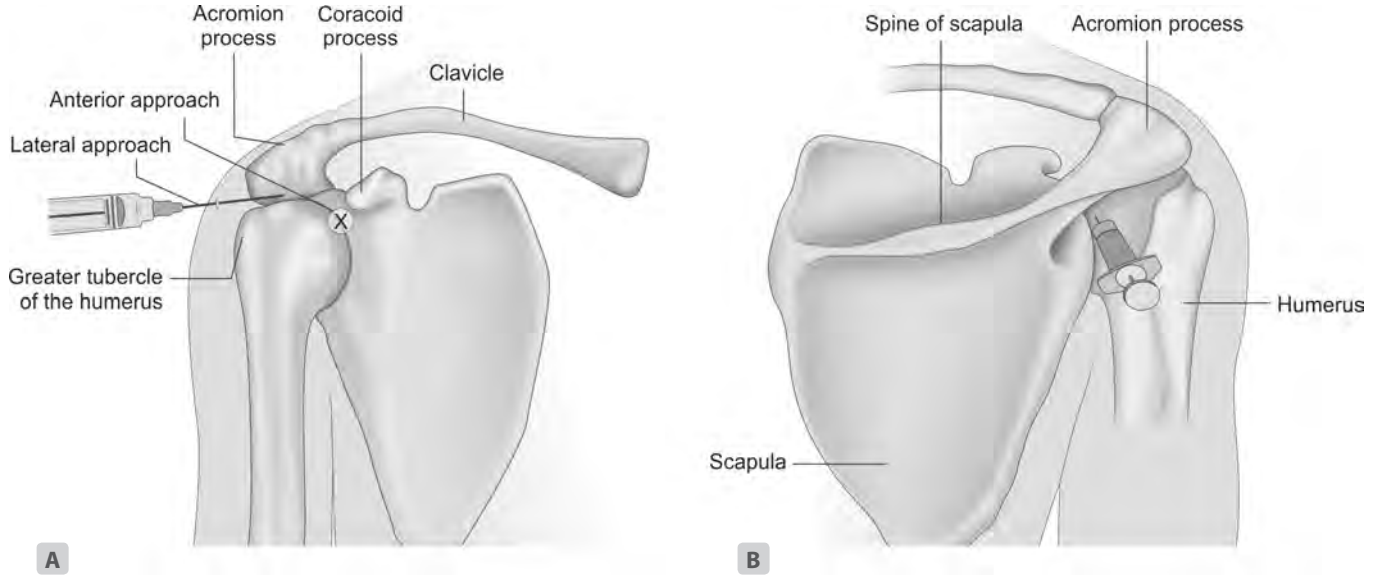
Intra-articular Injection and Aspiration

Each intra-articular injection should be performed in a sterile fashion to minimize the risk of introducing infectious pathogens. Prepare the site with povidone iodine, chlorhexidine, or iso-propyl alcohol as per the institutional protocol. After each procedure, dress with clean gauze. Aspirations should be performed using an 18G/20G needle to allow aspiration of thick substances. Patients with larger body habitus may require the use of a longer spinal needle in order to get intra-articular access.

Shoulder—Anterior approach: Palpate the coracoid process on the anterior aspect of shoulder. Place a needle 1 cm lateral to the coracoid process and just medial to the head of humerus. Advance the needle posteriorly and angled slightly superolaterally. *In the posterior approach*, palpate the posterolateral corner of the acromion; two finger-breadths inferior and one fingerbreadth medial. The needle should be oriented obliquely from this point toward the coracoid process, which can be palpated with the anterior aspect of the shoulder (**Figs. 23A** and **B**).

Elbow—Lateral approach: On the lateral aspect of elbow, palpate the soft spot in the center of a triangle by three bony landmarks; (1) lateral epicondyle of the distal humerus, (2) radial head, and (3) olecranon. Enter the elbow joint from this point by staying parallel to the articular surface of the radial head. *Posterior approach*: With the elbow flexed to 90°, palpate the soft sport approximately 5 cm proximal to the olecranon process on the posterior aspect of the elbow (**Fig. 24**).

Wrist—Dorsal approach: It utilizes the interval between the third and the fourth extensor compartments of the wrist. Palpate Lister tubercle on the dorsum of the wrist. Insert the needle distal to the tubercle, at the level of the joint, between the extensor pollicis longus and the extensor digitorum



FIGS. 23A AND B: (A) Shoulder joint arthrocentesis (a) lateral approach (b) anterior approach; (B) Shoulder joint arthrocentesis posterior approach.

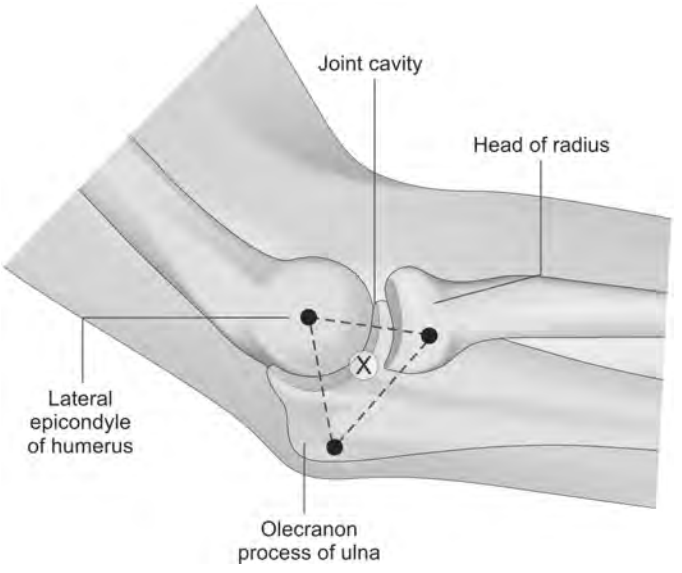


FIG. 24: Site of elbow arthrocentesis.

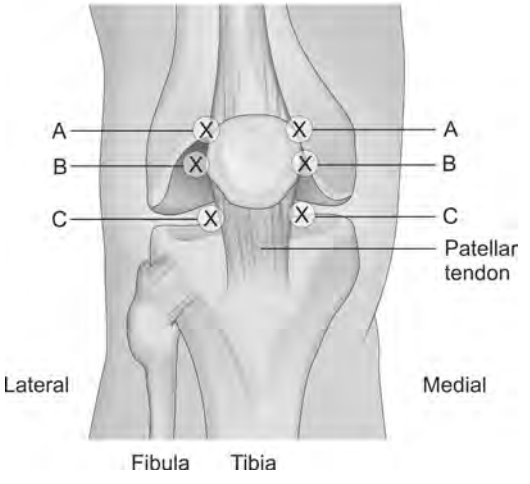

FIG. 25: Site for knee arthrocentesis.

communis tendons. Angle the needle distally to account for the volar tilt of the articular surface. *Medial approach*: Palpate the soft spot between the extensor carpi ulnaris and the flexor carpi ulnaris of the medial aspect of the wrist. Pass the needle between the tendons distal to the ulnar styloid.

Ankle: An anteromedial approach to the ankle is a must. The patient should be positioned supine and the anterior ankle prepped in a sterile fashion. Identify the tibialis anterior tendon at the level of the joint and introduce a 20G needle medial to the tendon. Angle the needle caudal to account for the slope of the dome of the talus.

Knee—Anterolateral approach: Same site as the lateral portal for knee arthroscopy. With the knee flexed to 90°, palpate the lateral joint line and borders of the patellar tendon. Palpate the soft spot lateral to the patellar tendon and above the joint line. Pass the needle superomedially, into femoral the notch. *Superolateral approach*: Mark the superolateral corner of the knee with the patient supine and knee fully extended. With one hand sublux the patella laterally as the needle is passed deep into it, toward the femoral notch (**Fig. 25**).

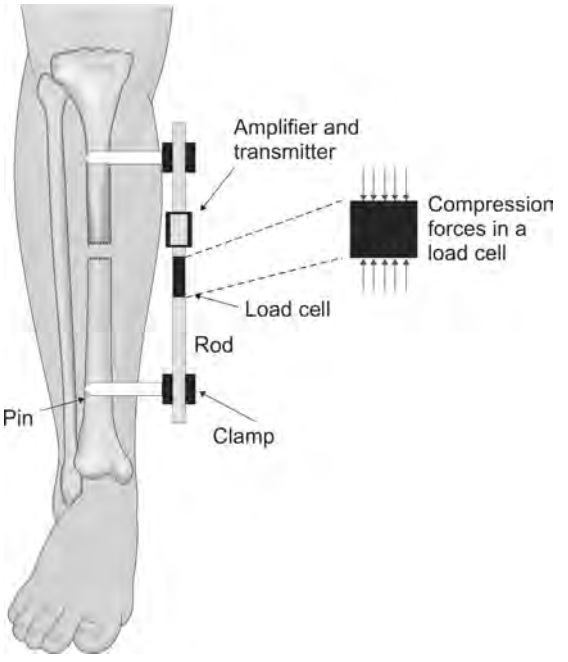

FIG. 26: External fixator.

EXTERNAL FIXATOR, PELVIC BINDER, EXTERNAL PELVIC FIXATOR

External Fixators

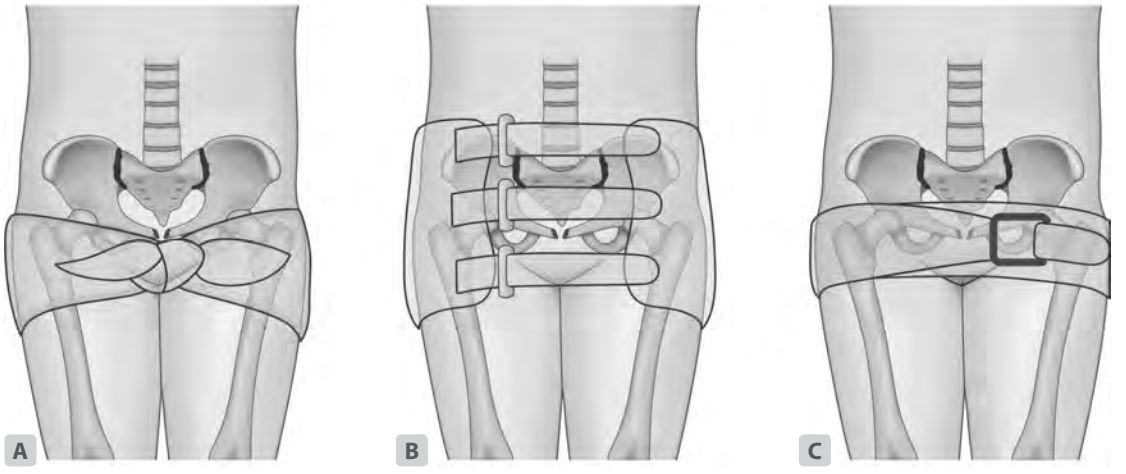
External fixators are used to maintain the length, alignment, and rotation of the fracture. This can be used as temporary or permanent. There are various types of external fixators, e.g., uniplanar, multiplanar, unilateral, bilateral, and circular. With absolute proper fracture stability, the external fixator promotes the bone healing process (**Fig. 26**).

Pelvic Binder

It is a device to compress the pelvis in those with a pelvic fracture in an effort to stop bleeding. It is specifically recommended for open-book pelvic fractures. A bedsheet or anything which is noncompressible and nonelastic may be used as well. The device should be placed over the upper femur, specifically over the greater trochanters. It is used only for short term. Skin ulceration may develop with long-term use. Open pelvic fractures, perineal lacerations, intra-abdominal injuries requiring surgery, morbid obesity, burns, and severe pelvic soft-tissue injury are the relative contraindications for pelvic binder placement (**Figs. 27A** to **C**).

External Pelvic Fixator

It is used as a damage-control orthopedics modality for fracture stabilization to prevent bleeding from the surfaces of pelvic bones. The fixator provide pelvic stabilization, by reducing the pelvic volume and bleeding from the stumps of fracture; it determines the arrest of the hemorrhage. There is containment of retroperitoneal hematoma. It reduces bleeding from the fracture fragments and the motility of the fracture, promoting the clotting of blood. Necessary equipment are sterile tray with drapes, Schanz pins, local anesthetic (2% lignocaine),



FIGS. 27A TO C: Pelvic binder.

T-handle, povidone-iodine cleansing solution, drill bit (3.2 mm) and handheld power drill, external fixator rods-external fixator clamps, spanners to tighten the clamps, and dressing material to cleanse and dress the pin sites.

SUMMARY

Orthopedic injuries following trauma are common presentations in the emergency department. Various procedures related to orthopedic injuries are performed to stabilize the patient. There are various orthopedic procedures which an emergency physician should know: Splinting, casting, reduction of dislocation, arthrocentesis, application of pelvic binder. The emergency physician should be aware of the indications, contraindications, and complications of the common orthopedic procedures.

233
CHAPTER

Geriatric Trauma

Devendra Richhariya

INTRODUCTION

Emergency physicians face a unique set of challenges while managing elderly patients with trauma. Older patients are more vulnerable to trauma due to the combination of comorbid health conditions, prescribed medications, and frailty which increases the chances of subsequent complications, including infections, pneumonia, venous thromboembolism, and multisystem organ failure. Patients > 65 years old with trauma show an increase in mortality rate as compared to younger patients with similar injury severity score (ISS). It has been observed that elderly patients are undertriaged in most of the time and trauma care gets delayed. Any patient older than 70 years of age with trauma should be treated in the trauma unit as mortality increases 7% for every year beyond age 65 years. Apart from challenges during management, a physician has to face more significant obstacles to recovery than younger patients but most elderly trauma patients return to independent or preinjury functional status despite overall higher mortality, longer hospitalization, increased resource use, and higher rates of discharge to rehabilitation. The most important aspect in improving outcomes in elders with trauma is understanding the fact similar trauma principles apply to the elderly, with more aggressive evaluation and resuscitation. This chapter provides insight into the challenge of treating geriatric patients with trauma, covering differences in anatomy and physiology, triage, and resuscitations as well as addressing some special situations, including elder abuse, hypothermia, and suicide.

GERIATRIC ANATOMY AND PHYSIOLOGY

Frailty, Aging versus Underlying Disease

Mortality after trauma increases with age, but chronologic age is less important in trauma than frailty. Frailty is defined as impairment of the function of multiple systems that increases the susceptibility to physical and physiologic stressors. Quantification of frailty is difficult because of the long and time-consuming tools, which difficult to apply in the emergency setting. The patient's baseline functional status and evidence of sarcopenia may be considered as surrogate markers of frailty. Frail patients with multiple comorbidities have poor functional status and have worse outcomes after trauma.

Head and Neck

The leading cause of traumatic death in the elderly is due to traumatic brain injury. The brain shrinks with an increase in age and is more susceptible to tearing and bleeding from the shearing forces in trauma as decreasing brain volume causes stretching of the bridging veins. With increase in age, cerebrovascular autoregulation and free radical clearance are also impaired which further worsens brain injury in elderly patients and also delays recovery. Elderly patients if taking oral anticoagulants (OACs) are at a higher risk for significant intracranial bleeding in case of even minor head trauma. Thus, the clinician should have a lower threshold for computed tomography (CT) scan imaging in patients >65 years old with even minor head injury.

Cardiac

Elderly patients with congestive heart failure (CHF), and those on warfarin or β-blockers, have diminished cardiac reserve and are at a higher risk of poor outcomes after trauma. Structural and functional cardiac changes during aging lead to decreased reserve and a further significant reduction in cardiac function during the stress of trauma. There are no clear studies to guide management in the emergency department (ED) but during the evaluation of a geriatric trauma, careful cardiac examination and medication history should be performed by the clinician. Inotropic and chronotropic medications should be considered in poor cardiac output and hypotension and balloon pump in severe refractory cases.

Pulmonary

The physiology and mechanics of breathing also alter with age. Impairment of respiratory muscle mechanics occurs due to an increase in chest wall rigidity and worsening kyphosis, and when associated with a weak diaphragm may lead to a decreased fraction of expiratory volume in 1 second (FEV1) and decreased vital capacity and result in an overall decline in respiratory reserve. Chronic obstructive pulmonary disease in the elderly also has diminished lung function due to underlying, pulmonary fibrosis, or scarring and elderly patients can have significant hypoxia at lower levels of physiologic stress. Elderly patients with trauma become

more susceptible to the stresses of acute blood loss and fluid resuscitation.

Abdomen

Liver and kidney disease: Ischemic, reperfusion injuries, and risk of hemorrhage are very high with the underlying renal, hepatic disease with cirrhosis. Susceptibility to post-trauma complications also increases in elderly patients with trauma. Elderly populations are more prone to contrast-induced nephropathy (CIN) due to increased incidence of kidney disease, which may make them. Elderly on oral hypoglycemic medications can increase the risk of CIN and need to communicate with the radiologist in view of limited scans with contrast to avoid iatrogenic harm. Elderly patients typically have less muscle mass, and a high normal value may reflect acute kidney injury or chronic kidney disease; thus, a normal creatinine level should be interpreted with caution.

Musculoskeletal

Fragile bones and skin: Elderly patients are more susceptible to fractures even in the absence of underlying osteoporosis due to expected physiologic changes to both muscle and bone. Older patients have a loss of muscle mass leading to sarcopenia and a subsequently decreased structural support; weaker bones and aging bones are more easily fractured with minor trauma, for example, in falls from standing. Sarcopenia is one of the defining characteristics of frailty syndrome. With increase in frailty, functional decline occurs, leading to decreased mobility and deconditioning, increasing the risk of falls and injury. The elderly are at an increased risk of musculoskeletal injury; thus, emergency physicians should have a low threshold of obtaining plain film radiographs. Advanced imaging such as CT or magnetic resonance imaging (MRI) of the hip should be recommended even with normal radiographs who are unable to walk after trauma.

HISTORY: MECHANISM OF INJURY

Falls

The rate of falls is increasing in the elderly and is a leading cause of trauma-related mortality. Elderly patients with falls generally need hospitalization and even intensive care, if complications occur, and subsequently require discharge to a rehabilitation facility. The elderly are more likely to die from secondary complications as a result of trauma and less likely to die as a direct result of the trauma. Traumatic brain injury (TBI) is the most common direct cause of death from a fall.

Risk Factors

The most important risk factors for falls and related sequelae of the falls are frailty and comorbidities. The pattern of injury is directly related to the mechanism. The exact cause of falls may be difficult to determine in an emergency setting as falls are often multifactorial. In the geriatric population, several risk factors of falls have been identified and many of these patients may have occult infections (**Table 1**). Gait abnormalities and slow reaction times due to underlying arthritis, poor vision, sarcopenia, and chronic medication may contribute to fall in the elderly.

TABLE 1: Risk factors responsible for geriatric trauma.

Acute illness	New medications, syncope, dysrhythmias, CVA, TIA, acute MI, seizure acute renal failure, infection, hypoglycemia, AAA, dehydration, acute fractures
Chronic medical conditions	Osteoporosis, osteoarthritis, CVA, ischemic heart disease, anemia, DM, HTN gait or balance impairment, visual impairment, depression, polypharmacy, Parkinson disease, dementia
Environmental factors	Rugs, lighting, stairs, bathtubs/showers, footwear, walking aids, uneven ground, weather, pets
Others	Older age, female alcohol or drug use, elder abuse

(AAA: abdominal aortic aneurysm; CVA: cerebral vascular accident; DM: diabetes mellitus; HTN: hypertension; MI: myocardial infarct; TIA: transient ischemic attack)

Sources: Adapted from Aschkenasy MT, Rothenhaus TC. Trauma and falls in the elderly. Emerg Med Clin North Am. 2006;24(2):413-32; Sattin RW. Falls among older persons a public health perspective. Annu Rev Public Health. 1992;13:489-508.

Motor Vehicle Collision

Older patients are more likely to have more severe injuries at low-speed motor vehicle crash (MVC) and are to be admitted to the intensive care unit. Number of geriatric patient with motor vehicle collision are increasing and because of higher mortality in these patient, they require hospitalization in level-I trauma center with good rehabilitation facilities.

Pedestrian Struck

Approximately 20–30% of geriatric pedestrians are struck and killed by a motor vehicle. The most important risk factors for elderly pedestrian trauma are decreased visual acuity, slow reaction times, and difficulty ambulating as well as impaired judgment. Even with minor or low-energy trauma, elderly patients are more prone to serious injury and a higher incidence of death as compared with younger patients.

CLINICAL WORKUP

Triage/History of Present Illness

In both the prehospital setting and the ED, geriatric patients with trauma are frequently undertriaged. Certain risk factors such as age, female sex, and a fall-related injury may lead to undertriage. In geriatric patients, due to common underlying comorbidities, use of certain medications can mask the physiologic effect of the trauma or exacerbate vital signs. General prehospital triage guidelines may be ineffective or unreliable. The risk of death increases with even minor deviations in normal vital signs. Heart rate (HR) >150 beats per minute and a systolic blood pressure of 90 mm Hg carry a higher risk of mortality. Even small changes in the Glasgow Coma Scale (GCS) score of 14 in geriatric trauma patients after TBI are associated with significantly higher mortality in comparison to younger adults with a similar GCS. Elderly

patients with trauma should be evaluated at a trauma center and the trauma team should be activated.

Injury Severity Score

Trauma severity scores are used to correlate injury with mortality in the elderly. Trauma score (TS) and revised trauma score (RTS), the two most useful scores, are used. In the ED, the TS is assessed on the basis of blood pressure, respiratory rate, respiratory effort, GCS, and capillary refill (score of 0–16) while RTS does not use respiratory effort or capillary refill (score of 0–8). In the triage of elderly trauma patients, RTS and TS may be useful tools although studies are mixed regarding their use. ISS is also used to predict mortality. It is a common practice to use ISS in triage but its applicability to elderly patients is debatable. Even minor trauma in elderly patients is extremely susceptible to the adverse outcome, so history should be taken very carefully. There is no consensus of using the triaging scale in geriatric trauma so the combination of TS and RTS can be used along with clinical impression age, and other physiologic parameters should be taken into account. Certain underlying disease processes include heart disease, peripheral arterial disease, coagulation disorders, malignancy, and obesity and affect clinical outcomes in geriatric patients with multitrauma.

Past Medical History/Medications and Reversal Agents

When taking the history, it is important to note the medications such as β-blocker and OAC that are used before a traumatic event. Patients taking a drug combination of β-blockers, calcium channel blockers, and an angiotensin-converting enzyme inhibitor or angiotensin receptor binding agent can mask hemodynamic responses to trauma. The elderly who are on antihypertensive and sedatives increase the risk of trauma, due to falls. Many common conditions, including atrial fibrillation, stroke, thromboembolism, and medical management, after cardiac revascularization require OACs such as warfarin, rivaroxaban, apixaban, dabigatran, clopidogrel, and aspirin prescription for a longer duration. Patients who are on OACs are at a greater risk of intracranial hemorrhage following head injuries and increased risk of hemorrhage after intra-abdominal injuries. In the setting of intracranial or intra-abdominal hemorrhage, rapid reversal of the international normalized ratio (INR) slows the progression of the bleed and reduces mortality.

INITIAL MANAGEMENT AND RESUSCITATION

As in any other patient, initial resuscitation should begin with ABCs (airway, breathing, and circulation). Supplemental oxygen should be placed in all trauma patients to preoxygenate, and endotracheal intubation becomes necessary for an apneic patient. Various physiologic and structural changes with increasing age like rigid cervical spine, poor dentition, and high Mallampati score makes the bag mask ventilation and endotracheal intubation difficult. Degenerative changes of jaw causes incomplete opening of the mouth which makes intubation further more difficult. Mechanical ventilation also become difficult due to decreased functional reserve. Rapid-sequence intubation (RSI) medicine doses should be adjusted in the elderly if intubation is required (**Table 2**). To decrease the hemodynamic effects of benzodiazepines and etomidate, doses should be reduced by approximately 20–40% in the elderly. Ketamine should be used with caution in patients with ischemic heart disease because it increases myocardial oxygen demand. Complete exposure of the patient and a quick neurologic assessment should be performed under the secondary survey. Due to decreased pain perception and cognitive decline, physical and abdominal examination may be more difficult and unreliable in elderly patients. Similarly, underlying dementia or altered mental status from other causes, such as infection or stroke, make neurologic examination complicated. Thus, even with minor trauma, liberal use of CT scans is appropriate.

TABLE 2: Rapid-sequence induction medications and suggested dose adjustments.

Medication	*Adjustment*
Succinylcholine 1.5 mg/kg IV	No change
Etomidate 0.1–0.2 mg/kg IV	Decreased from 0.3 mg/kg IV
Midazolam	Decrease 20–40%
Fentanyl	Decrease 20–40%
Ketamine	Should be avoided secondary to cardiac effects

Do-not-resuscitate Status

It is critical to consider the patient's wishes; during resuscitation, consider the possible futility of such resuscitation but age alone should never be used as the sole determinant to limit care. The risk of mortality increases with the presence of certain risk factors, including hypotension, age >74 years, and higher ISS.

Assessment for Unstable Patients

In all unstable elderly patients with trauma, aggressive resuscitation should be initiated. All elderly should be considered unstable if they present with persistently abnormal vital signs or are not responsive to resuscitation efforts and those who have evidence of active hemorrhage or deteriorating mental status. Apparently stable geriatric trauma patients should be thoroughly evaluated for occult life-threatening injuries. In elderly patients with trauma, abnormal values of the serum lactate level and base deficit indicate impending deterioration and may predict mortality. After initial resuscitation, persistently abnormal values of serum lactate and base deficit values should be repeated. Hemodynamic monitoring in the elderly patients with trauma is essential. Ultrasonography and echocardiography have widely replaced the use of pulmonary artery catheters. Even slight changes in hemodynamic (HR, blood pressure) in geriatric trauma may signify occult injury and should be investigated thoroughly.

Reversing Anticoagulants

A patient's INR, activated partial thromboplastin time, and prothrombin time should be assessed and reversed promptly if any abnormalities are found in the geriatric trauma patient. Fresh frozen plasma (FFP) or prothrombin complex concentrate

TABLE 3: Anticoagulants and potential reversal agents.

Anticoagulation agents	*Mechanism of action*	*Potential reversal agents*
Warfarin	Vitamin K antagonist	FFP, PCC, vitamin K
Dabigatran	Direct thrombin inhibitor	Idarucizumab
Rivaroxaban	Factor Xa direct inhibitor	PCC
Apixaban	Factor Xa direct inhibitor	PCC
Enoxaparin	Antithrombin III inhibitor	Protamine (partially effective)
Heparin	Antithrombin III inhibitor	Protamine

(FFP: fresh frozen plasma; PCC: prothrombin complex concentrate)

(PCC) and vitamin K may be used for rapid reversal in patients with an increased INR. Normalization of prothrombin time or INR does not always correlate with decreased bleeding. The newer anticoagulants such as rivaroxaban, apixaban, and dabigatran do not yet have proven reversal agents; however, some studies show that PCC may be a reasonable choice with life-threatening bleeding (**Table 3**). Monoclonal antibody reversal agents for rivaroxaban, apixaban, and edoxaban are being investigated. Idarucizumab, a monoclonal antibody, for the reversal of dabigatran in the setting of an acute bleed has been recently approved by the US Food and Drug Administration.

DIAGNOSTIC EVALUATION

Neurologic or cardiac events are more common in the elderly population; thus, thorough assessment of the fall is critical. In the event of geriatric trauma, environmental factors, substance use, acute or chronic medical conditions, medications, and the patient's baseline functional capacity should also be assessed and investigated carefully. An appropriate investigation like electrocardiogram plain films or CT scanning of the affected organ systems should be done in all elderly patients with trauma. Elderly patients do not always experience the same degree of pain relative to the severity of injury; thus, radiology use should be liberal. In elderly patients with trauma with moderate-to-severe mechanisms, FAST (focused abdominal sonogram in trauma) examination is quick and easy to perform. Elderly patients should undergo whole-body CT scan when there is evidence of multisystem involvement.

Head Injuries

The TBI is the fifth leading cause of death in the elderly and as a result of low impact, ground-level falls. Geriatric patients with TBI require longer hospital admissions and more intense rehabilitation after discharge after a head injury as compared with young patients. Even minor changes in GCS of 14 have 10–15% mortality in a geriatric patient; any patients >60 years of age with loss of consciousness or who are taking an OAC should undergo a brain CT scan. Elderly patients with minor head injury who are taking OACs and have a normal brain CT scan may be safely discharged because of the low risk of bleeding but they should be given clear instructions.

Cervical Spine Injuries

Similarly, elderly patients after trauma are at an increased risk of cervical spine fractures. As a result of degenerative changes and stiffening of the cervical spine in the elderly, cervical spine (C1–C2) and odontoid fractures are twice as likely to have a cervical spine injury (CSI) as younger patients with the same mechanism of injury. Geriatric patients may have CSI with lower energy mechanisms of injury so application of the National Emergency X-radiography Utilization Study (NEXUS) decision rule in the elderly has been debated. It is recommended that a CT scan of the cervical spine be obtained if CT scan of the brain is ordered because the concomitant risk of CSI is high.

Thoracic Trauma

Even with isolated rib fractures, blunt thoracic trauma in the elderly carries a significant risk of complications and mortality. Pneumonia and pulmonary contusions are the most common complications following thoracic trauma in the elderly. Factors helpful in predicting adverse outcomes are age >85 years, initial systolic blood pressure of <90 mm Hg, three or more unilateral rib fractures, or the presence of pneumothorax, hemothorax, or pulmonary contusion. Dispositions should be carefully considered in an elderly patient with one or more rib fractures because of the high risk of mortality.

Musculoskeletal Injuries

Musculoskeletal injuries carry a risk of osteoporosis, and subsequent fractures are very common in elderly patients with trauma. A geriatric patient with fracture negatively affects both the patients' quality of life and the society at large. Forearm fractures are the most common, with hip fractures a close second in the geriatric population. A dedicated orthogeriatric team approach with early surgical repair, balanced with medical optimization, significantly improves the chance of patients in returning to their previous functional states and may improve outcomes for these patients.

Elderly patients with pelvic fractures and lateral compression fractures are likely to require angiography and blood transfusion due to the increased risk of hemorrhage. In older patients with pelvic fractures, even with appropriate treatment and disposition, mortality remains high so these patients should be aggressively resuscitated.

SPECIAL SITUATIONS

Elder Abuse

Elder mistreatment or abuse can be defined as intentional actions that cause harm or create a serious risk of harm, whether or not intended, to a vulnerable elder by that person's caregiver or by a trusted person in relation to that elder. Failure

of the caregiver to satisfy the elder's basic needs or to protect that person from harm is also considered as elder abuse. Nearly one fourth of elders are affected by psychological abuse. An emergency physician should ask about the potential abuse of elderly patients because they often report it if asked.

Risk factors and types of elder abuse: Elder abuse is a global problem. Dementia is one of the greatest risk factors for elder abuse. Older women with disabilities are at a significant risk for interpersonal violence. Financial, emotional, and both physical neglect and sexual abuse are also other types of elder abuse.

Health impact of elder abuse: Geriatric population has a higher incidence of bone and joint disorders, digestive problems, depression, anxiety, chronic pain, increased blood pressure, and a heart problem; thus, even modest abuse has an increase in risk of death compared with nonabused.

Management principles: *Assessment—a*n emergency physician should ask few screening questions to the elderly related to managing their daily lives or any psychosocial stress while performing daily activities because this is a risk factor for abuse. Ideally, the patient should be interviewed alone. Caregiver fatigue should also be assessed by taking his interview because this can increase the risk of elder abuse. The cognitive and functional status of the patient should be assessed; this should be addressed before discharging the patient. Until a preliminary investigation is conducted, there should be a low threshold for admitting these patients to get them out of their potentially abusive environments. If it is determined that the patient is experiencing abuse, a social worker should be involved, the case should be reported, and a safe environment should be established. Also, clinicians must try to facilitate treatment of the underlying disease, e.g., anxiety and depression, causing the patient at risk for abuse by caregivers.

DISPOSITION

A multidisciplinary approach should be taken while discharging or admitting patients. History of multiple falls, impaired mobility, poor strength, and depression increase the risk of a recurrent fall; thus, the involvement of social work, family members, and the patient's primary care physician is important. Acute underlying conditions should be evaluated and managed promptly before discharge. Several factors must be considered before discharge, including the cause of the injury, the patient's home environment, availability of helpers at home if the patient needed, and who will follow up with the patient. Admission should be considered to facilitate coordination of an appropriate care plan if a definitive discharge plan is not available.

SUMMARY

Geriatric patients with trauma will become increasingly common as the population ages. Mechanism of injury, injury types, morbidity, and mortality are unique in the geriatric population; if not treated aggressively, they are likely to have poor outcomes. Emergency medicine physicians and trauma surgeons should be familiar with the physiologic changes of aging and effects of potential underlying comorbidities on geriatric trauma and maintain a high index of suspicion for serious injury for all geriatric patients with trauma. Emergency physicians should be liberal with the use of laboratory and diagnostic imaging studies in geriatric trauma patients and should have a low threshold to admit elderly patients with trauma. Geriatric trauma patients deserve a more aggressive approach than younger patients who have similar mechanisms during their initial emergency management because aggressive care and resuscitation have a dramatic effect in improving outcomes in these patients.

CHAPTER

Approach to Pediatric Trauma

Nisreen Hamza Maghraby, Mohye Al Wahas, Samar Ahmad Al Nahash

INTRODUCTION

Injury remains the most common cause of death and disability in childhood. Each year, more than 10 million children—nearly one of every six children—in the United States require emergency department (ED) care for the treatment of injuries. Each year, more than10,000 children in the United States die from serious injury. Injury morbidity and mortality surpass all major diseases in children and young adults, making trauma the most serious public health and healthcare problem in this population. The mechanism of trauma is divided broadly into blunt and penetrating. As in adults, blunt trauma is more common. It results from falls, sports-related injuries, and motor vehicle collision (MVC). Most injuries are accidental, but nonaccidental traumas must not be missed. Clues include but not limited to history, physical examination, a changing history, bruises of different ages and bruises in <1 year of age; remember "if you cannot cruise, you should not bruise."

Evaluating the pediatric population is challenging, as they might not directly communicate with strangers. It is very important to be observant of what they can and cannot do on initial visual assessment.

It is important to understand that children will not move if the movement induces pain, so if they are brought in by emergency medical services (EMS) and strapped down on a board, they cry to get out. You can simply bring in the parents and start unbundling the child, being observant and supportive at the same time.

It is also important not to forget to offer parents to come in and observe the resuscitation efforts and to assign a member from the team to support them by explaining each intervention that is taking place. Studies have shown that it helps parents to accept the outcome and eases grief.

ANATOMICAL AND PHYSIOLOGICAL DIFFERENCES

Pediatric are not just small adults. There are multiple anatomical and physiological differences. The most relevant differences that must be understood when managing a pediatric trauma patient are as follows:

- Greater physiological reserve, so they are able to maintain blood pressure, despite 25–30% blood loss, and look for subtle changes in heart rate, blood pressure, and extremity perfusion always refer to the normal range according to age.
- Airway interventions could be challenging due to relatively larger tongue, floppy and U-shaped epiglottis, anterior/cephalad larynx, shorter tracheal length, and the cricoid ring being the narrowest portion.
- Serious head injuries are a result of greater head to body ratio and thinner cranial bones, and the brain is less myelinated.
- Intrathoracic injuries are more likely as the ribs are more compressible dissipating the force of impact and decreasing the likelihood of bony injuries.
- Solid organs (liver and spleen) are less protected by muscle mass, are more anteriorly placed, and have less subcutaneous tissue thus making them prone to injuries, but the protective elastic capsule around both these solid organs leads to subcapsular injuries/hematomas and less lacerations with free fluid (blood) in the abdomen.
- Kidneys are susceptible to deceleration injuries, as they are less protected and more mobile; despite that, 15% of pediatric patients with hematuria post-trauma have congenital anomalies.
- Multiple traumas are common due to small body size leading to greater distribution of the injuries.
- Greater relative body surface area relative to the weight lead to greater heat loss and predispose them to hypothermia.
- Extremity fractures could possibly result in limb-length abnormalities as the growth plates are not closed and the most common fractures are Salter-type fractures.
- Higher caloric and energy requirements are a result of higher oxygen consumption and glucose utilization.
- Age- and weight-adjusted fluid and medication doses should be considered and clinicians should be familiar with length-based resuscitation tapes and their uses.

EVALUATING A PEDIATRIC TRAUMA PATIENT

A complete trauma evaluation has three surveys, each with a separate goal:

1. *Primary survey*: To identify the killers. Follow the evaluate, identify, and intervene approach.

2. *Secondary survey*: To identify major musculoskeletal (MSK) injuries or dislocations.
3. *Tertiary survey*: Final review of the laboratories and radiological imaging and screening before the patients are cleared to go home.

Prevent and Identify the Killers in Trauma

The killers can be described by two different approaches:

- *Physiology*—lethal triad of trauma (**Fig. 1**) prevent hypothermia, acidosis, and coagulopathy.
- Pathology—the HOTT mnemonic (**Fig. 2**), identify and treat these: H: Hemorrhage, O: Oxygenation, T: Tension pneumothorax, T: Tamponade (pericardial hemorrhage).

Receiving the Patient

If the patient was brought by EMS, he/she is most likely to be on a backboard. This board must be removed immediately; backboards are for transportation only. They are not a benign intervention. They lead to pain, pressure, and wounds and are simply uncomfortable.

Before the paramedics leave, you must ask four main questions, which are summarized in the mnemonic MIST, M: Mechanism of injury, most importantly was the patient restrained or not, where was he/she found (ejection mechanism), blood or death on the scene; I: Injuries found or suspected; S: Vital signs on scene; and T: Treatments given, when and how much. The patient must be connected to a monitor immediately and undressed into a hospital gown to easily evaluate the patient. A line should be secured; the size of the line should consider the patient's situation (unwell large line, well no line or small line) and a venous blood gas (VBG) sent. Additional samples can be kept. Ultrasound (US) should be ready to be used for evaluation.

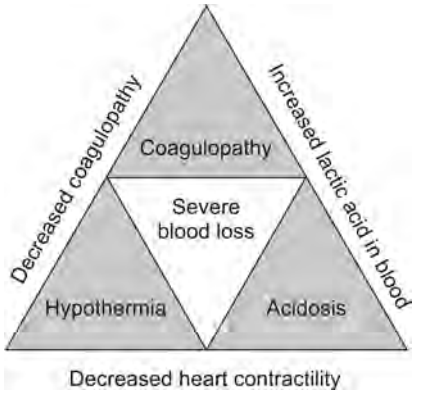

FIG. 1: Lethal triad.

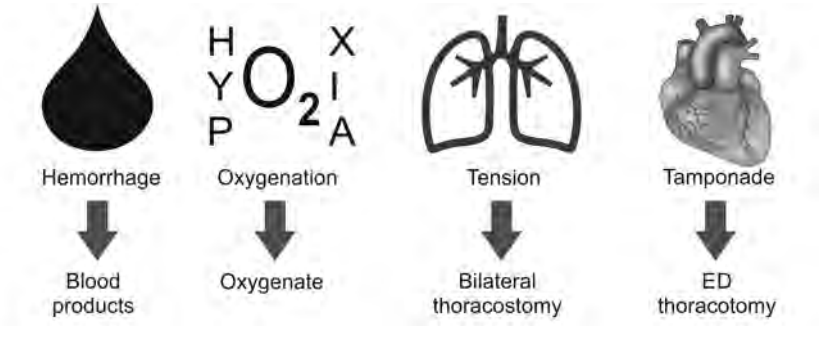
PRIMARY SURVEY

The primary survey is a quick scan to evaluate the patient for the killers; your quick screen should follow the traditional airway, breathing, circulation, disability, exposure (ABCDE) approach:

- *A*: *Airway and C-spine precautions*—the airway must be evaluated immediately for possible airway obstruction or a pending obstruction. Look for blood in or around the mouth, look at the floor of the mouth for a hematoma, check the teeth for missing or loose teeth, check if there are any vomitus stains, check if the patient is controlling his saliva, and listen for gurgling sounds or any stridor. If you need to open the airway, perform a jaw thrust maneuver as it is less likely to lead to C-spine movements. Use airway adjuncts or apply oxygen via a face mask as needed. The main purpose of airway evaluation is to determine if the patient is able to protect the airway or not.
  Regarding the C-spine: Always attempt to clear the C-spine clinically whenever possible. Remember C-collars are again not a benign intervention. They lead to pain, discomfort, and predispose the patient to aspiration if they vomit and increase work on the nurses. There are a few clinical decision rules (CDR) to help clear the C-spine clinically. Nexus is the one that included pediatrics. If the C-spine could not be cleared clinically, then the imaging of choice is a computed tomography (CT) scan and not an X-ray and the patient must remain in the C-collar until the report is negative for any C-spine fractures. The patient may be kept in a reverse Trendelenburg position for comfort. After that, the patient must be re-evaluated by passively allowing the patient to rotate his head to evaluate the range of motion to roll out ligamentous injuries. During this re-evaluation, there is no role in palpating the C-spine as palpation is an indirect sign to assess for bony injuries and they have already been rolled out by a gold standard test (CT scan). If the patient is unable to rotate his/her neck, then he/she must remain in a collar and be referred to neurosurgery for magnetic resonance imaging (MRI) to roll out ligamentous injuries. Spinal cord injury without radiographic abnormality (SCIWORA) is the term used to describe spinal cord injuries without radiographic abnormality. It is suspected in patients with neurological deficits, including transient paresthesia, numbness, or



(ED: emergency department)

FIG. 2: Approach to cardiac arrest.

paralysis, without any radiological finding, more common in <8 years of age; in this case, MRI is the best diagnostic modality. *Endotracheal* (*ET*) *intubation is indicated mainly for*: Oxygenation, ventilation, and protection of the airway from an anticipated deterioration in the clinical situation. Indications for intubating pediatric trauma patients are:

- Glasgow Coma Scale (GCS) score <8
- Inadequate oxygenation or ventilation—poor effort or color
- Inability to maintain or protect airway—gag reflex not especially helpful because it does not correlate with GCS
- Inability to ventilate by bag-valve-mask (BVM) or need for prolonged control
- Severe head injury
- Potential for clinical deterioration (thermal inhalation injuries)
- Respiratory failure from flail chest
- Decompensated shock resistant to initial fluid resuscitation.

Few anatomic differences should be kept in mind while dealing with pediatric airway (**Table 1**).

Selection of the ET tube size should be determined by a length-based resuscitation tape or age-based calculation: Uncuffed: 4 + 1 (age in years/4), Cuffed: 3.5 + 1 (age in years/4)

- *B*: *Breathing*—breathing is evaluated by looking at the oxygen saturation and the respiratory rate (RR), auscultating the chest, and observing chest wall movements. A fast RR may be an indirect sign of occult shock. The chest must be palpated, looking for any pain or grimacing that might be generated in addition to palpating for any subcutaneous emphysema. If the patient was identified to need intubation during the assessment of airway, preparation must be done immediately, but not performed until breathing is evaluated. We must make sure that the patient does not have a pneumothorax that could be converted into a tension pneumothorax with positive-pressure ventilation. Point-of-care lung US [extended focused assessment with sonography in trauma (eFAST)] should be done to mainly look for lung sliding, which is more sensitive than a chest X-ray. Never the least, a chest X-ray is still required to look for lung contusions and for follow-up and documentation. It is important to remember that hypoxia produces agitation and hypercarbia leads to central nervous system (CNS) suppression (drowsiness). *Surgical airway* (needle cricothyroidotomy in small children and infants, surgical cricothyroidotomy in >12 years of age) *is indicated in cases of failure of ventilation and intubation*.
- *C*: *Circulation*—evaluation of circulation is mainly done to identify hemorrhage that may lead to hemodynamic instability. Multiple data points must be collected as the gold standard to identify hemorrhage is a CT with contrast (trauma protocol). This leads to a large radiation and contrast exposure; timely identification is important before major compromise in blood pressure occurs as it will be an unsafe transport to the CT scan department at that point. Multiple data points that could determine possible hemorrhage include tachycardia, tachypnea, cold/clammy, prolonged capillary refill, confusion, shock index > 0.9, or a delta shock index > 0.1 (difference between SI on scene and in the ED) and a negative base access on the VBG. It is also important during this time to check on the size and site of intravenous (IV) access. The patient must be exposed down to the skin, to look for any signs of trauma indicating a concerning mechanism. It is during this time that any pressure dressings applied prehospitalization can be removed as before inserting an IV line or checking the blood pressure, it could be unsafe, especially if it was controlling an active hemorrhage and suddenly without preparation it starts to bleed. IV access in antecubital area is the preferred site and if it fails the intraosseous route can be used. The pelvis should be examined for any instability; if unstable, it should be wrapped immediately. An eFAST scan is then performed to look for free fluid in the abdomen. It is important to remember that a focused assessment with sonography in trauma (FAST) scan is only able to identify hemorrhage intra-abdominally. We have mentioned that a CT scan is the gold standard to identify injuries. In pediatric age group if child is complaining of abdominal pain, the ultrasound abdomen can be done before requesting a CT scan. As mentioned above, subcapsular hematomas in solid organs are common in pediatric and can be evaluated by a formal US. It is important to mention that if a trauma patient requires fluids, blood is the fluid of choice. One bolus of crystalloid might be given till blood arrives.
- The areas where a patient might bleed (chest, abdomen, retroperitoneal, and long bone fracture) which lead to hemodynamic instability are summarized in a mnemonic (four plus the floor), but in the <1-year-old population the head is an additional area (due to the ability of the skull to expand and accumulate enough volume).
- *D*: *Disability and dextrose*—despite being the last component of the primary survey, attempting to sedate and intubate a patient should never be done before evaluating the level of consciousness and looking for lateralizing signs. This can be done by asking the patient to simply passively move both his upper and his lower extremities or by applying a painful stimulus if the patient is not responding. The level of consciousness can be evaluated using the GCS (pediatric version) or the alert, voice, pain, unresponsive (AVPU) scale. Attention to the pupils (size/reactivity) should not be overlooked. It is important to take

TABLE 1: Anatomic difference of pediatric airway.

Airway differences	*Interventions*
Prominent occiput	Use a rolled towel under the shoulders
Larger tongue, larger adenoid tissues	Optimize head positioning, jaw-thrust position, use of an oropharyngeal airway
Floppy, U-shaped epiglottis	Use of a straight blade
Larynx more anterior	Positioned yourself closer to the patient at a 45° angle
The cricoid ring is the narrowest portion of the airway	Have a smaller sized tube ready because the larger sized tube may pass the cords but not the cricoid
Narrow tracheal diameter and distance between the rings	Must do needle cricothyrotomy rather than surgical
Shorter tracheal length resulting in frequent right-mainstem intubations or dislodgement	Use three times the tube size to estimate the accurate depth of placement, minimize head movement once placed

this chance and look externally at the head for any signs of head trauma. Generally, frontal hematomas are benign as the frontal bone is stronger due to a double cortex. Unlike temporal hematomas, frontal hematomas should be taken seriously for a possible significant head injury. The main concern after any head trauma is the likelihood of a significant head injury. That does not mean that a CT scan should be done for all head traumas. Again, there are a few CDRs to help guide that decision. Pediatric Emergency Care Applied Research Network (PECARN) is the most commonly used. Sharing the decision with the family is extremely important, but more important is to explain the benefits and risks to help them make an informed decision, in addition to providing them with a sheet for head trauma instruction if they decide to go home.

- *E*: *Exposure*—at the end of the primary survey, remember to expose the patient and perform a log role to make sure that there are no hidden injuries that have not been identified or no bandages or splints that have not yet been removed. Check a temperature, especially if the context of the situation has exposed the patient to possible hypo- or hyperthermia.

Adjuncts of the Primary Survey

Chest X-ray and VBG should be done and a Foley catheter should be inserted if the patient is intubated. Pelvic X-rays are not a routine requirement. If the patient has a GCS of 15, no distracting injuries or intoxication or no pain or tenderness, then a pelvic X-ray is not required.

TABLE 2: Indications of CT scan in pediatric trauma.

Pediatric age	*Indication of CT scan*
Children < 2 years of age	• Age < 3 months • Palpable skull fracture GCS < 14 • Agitation, irritability, somnolence, slow response • Scalp hematoma (temporal, parietal, temporal) • Loss of consciousness > 5 seconds • Fall > 3 feet, high-energy head impact • Motor vehicle collision with passenger ejection, rollover, or death of another passenger • Unhelmet pedestrian or on the bicycle
Children > 2 years of age	• GCS < 14 or any signs of altered mental status • Signs of basilar skull fracture • Battle sign—ecchymosis of the mastoid process • Raccoon eyes—periorbital ecchymosis • CSF otorrhea or rhinorrhea • Headache, vomiting, loss of consciousness • Fall > 3 feet, high-energy head impact • Motor vehicle collision with passenger ejection, rollover, or death of another passenger • Unhelmet pedestrian or on the bicycle

(CSF: cerebrospinal fluid; CT: computed tomography; GCS: Glasgow Coma Scale)

SECONDARY SURVEY

The secondary survey is basically a head-to-toe examination, palpating every single bone to identify injuries. It is important to range all joints in the range of motion, to roll out any dislocations. If a fracture is suspected, request an X-ray with a joint above and below. Confirm if there is any breakdown in the skin, as the management for an open fracture defers from a simple fracture. Check the pulse and evaluate the sensory and motor components of the nerve supplying that area, to confirm that neurovascularly the limb is intact. Address the pain and start with acetaminophen, nonsteroidal anti-inflammatory drug (NSAID) and then opioid if needed. If the patient has wounds, irrigate them, examine their size, and type of destruction to determine the need for antibiotics. Tetanus is usually not required in pediatrics, especially if their vaccines are up to date.

Children should not be exposed to unnecessary radiation. PECARN head injury guidelines were developed for obtaining a CT scan in the setting of pediatric head trauma based on symptomatology (**Table 2**).

Secondary Survey of Cervical Spine

Anatomic difference in the pediatric cervical spine: The pediatric age group is more susceptible to upper cervical injury because of certain anatomic differences. These anatomic differences of the cervical spine are as follows:

- Larger head size and weight compared with the neck and trunk
- Weaker C-spine musculature
- Increased laxity of the spinal ligaments
- Immature vertebral joints and ossification centers
- Increased elasticity of the spinal column
- Lack of uncinate processes until approximately 10 years of age.

Any child involved in a trauma with the potential for a C-spine injury should be treated as if the injury exists until proved otherwise, either by physical examination or by radiography. The C-spine should be adequately immobilized as soon as possible, ideally in a prehospital setting. The indications for spinal cord immobilization are given below:

- High-risk mechanism (MVCs, diving, contact sports, acceleration-deceleration injury)
- Altered mental status
- C-spine midline tenderness
- Decreased range of motion
- Neurologic deficits
- Distracting injury
- Multiple system trauma.

Secondary Survey of Cardiothoracic Trauma

Due to the differences in pediatric anatomy and physiology, injury patterns as a result of thoracic trauma in children are different from those seen in adults. Pediatric chest wall is able to absorb and distribute forces resulting in fewer rib fractures than the adult. But this compliance of pediatric chest wall may mask serious underlying chest injuries. Important features to look for in pediatric chest trauma are as follows:

- *Respiratory:* Abnormal rate, nasal flaring or retractions, paradoxical chest wall movement, chest wall injuries or defects, abnormal lung sounds on auscultation.
- *Cardiac*: Distant or muffled heart tones, murmur, irregular rhythm, distended neck veins.

- *Commotio cordis*: This condition is specially attributed to pediatric trauma. Commotio cordis is a combination of ventricular fibrillation and sudden cardiac death secondary to a sudden impact to the anterior chest wall.

Secondary Survey of Blunt Abdominal Trauma

Blunt trauma abdomen in the pediatric age contributes to significant mortality. The extent of injury in a child with blunt abdominal trauma is often difficult to determine. The intra-abdominal injury should be considered in any child with trauma until proved otherwise. The gold standard investigation after a trauma, for identifying intra-abdominal injury, is an abdominal CT scan with IV contrast in hemodynamically stable patients. The indications for obtaining an abdominal CT scan are as follows:

- History suggestive of severe intra-abdominal injury
- Physical examination concerning for intra-abdominal injury (i.e., abdominal tenderness, guarding, or rebound tenderness)
- Presence of the seat belt sign or other abdominal bruising
- Aspartate aminotransferase (AST) > 200 or alanine aminotransferase (ALT) > 125
- Decline in hemoglobin or hematocrit <30% from baseline
- Positive FAST examination
- Gross or microscopic blood on urine analysis [>50 red blood cells (RBCs)].

The majority of children with acute abdominal trauma are managed conservatively. Children with hemodynamic instability should be admitted to an intensive care unit for continuous monitoring and for volume resuscitation. A pediatric surgeon should be involved. Indications of emergency laparotomy after blunt abdominal trauma are given below:

- Intra-abdominal bleeding with persistent hemodynamic instability despite aggressive crystalloid and blood transfusion (transfusion > 20 mL/kg packed RBCs)
- Perforation of a hollow viscous injury leading to pneumoperitoneum
- Increasing abdominal tenderness or the development of peritoneal signs on examination
- Solid-organ injury with persistent bleeding
- Pancreatic injury with ductal disruption.

TERTIARY SURVEY

If the patient is intubated or will require admission, then the tertiary survey is deferred till predischarge. The aim is to make sure that the patient is able to function at baseline. All vital signs, laboratories, and imaging are reviewed; follow-up plans are set by the admitting team and any prescription, if required, is ready. The patient must be symptom-free, tolerating PO and ambulating at baseline. Clear discharge instructions must be given and what to expect. It is important to emphasize on the point that even if a CT of the abdomen was done, there are a few injuries that can be missed (mesenteric, bowel, diaphragmatic, and pancreatic). If the patient develops abdominal pain and fever and is unable to tolerate PO (vomiting), then they must return to the hospital immediately.

DISPOSITION

Most traumas are minor and patients are discharged from the ED. Others that are more severe are sent to the pediatric intensive care unit (PICU) for observation or postoperatively if an operation was required emergently. It is of note to mention that infants and children with moderate-to-severe injuries have improved outcomes in a PICU. So, if they were initially seen in an adult hospital, arranging for transportation should be considered. Remember that the role of an emergency physician is to evaluate and stabilize trauma patients prior to operating room (OR), PICU, or transfer to a tertiary care facility. Children with suspected abuse should not be discharged and involvement of concerned authorities should be done as they have high risk of fatalities.

SUMMARY

Various anatomical and physiologic differences are present between pediatric and adult population. These differences play a significant role while evaluation of a pediatric trauma patient. The emergency physician should be aware of these nuances while managing a pediatric trauma patient. A focused and structured approach should be used when dealing with children with traumatic injuries.

235
CHAPTER

Trauma in Pregnancy

Wael Hakmeh, Mustafa Sabak, Behçet AL

INTRODUCTION

Though pregnant female trauma patients presenting to the emergency department are few, they are associated with high morbidity and mortality. In critically injured patients, morbidly obese, and the first trimester of pregnancy, immediate recognition of pregnancy is not always possible. All women of childbearing age who present after trauma must be considered pregnant until proven otherwise. There are very few presentations in emergency; complex pathophysiology of pregnancy and dealing with two patients (mother and fetus) simultaneously must involve trauma team of emergency medicine specialist, obstetrician, and neonatologist. The specialist team can also deal with emotional and social issues very effectively. Although trauma management prioritizes the mother, the fetus must also be taken into consideration. Physicians should understand and anticipate the anatomical and physiological changes and potential injury patterns that occur in pregnancy. Other challenges while dealing with a pregnant trauma patient are multidisciplinary approach, exposure to radiation and teratogens, and management of pregnancy-specific problems.

ETIOLOGY

Trauma is the leading cause of nonobstetric maternal mortality, occurring in approximately 7% of all pregnancies, more often in the third trimester. Most frequently, it is caused by domestic violence and traffic accidents such as motor vehicle collision (MVC). Other forms of injury include penetrating injuries, slips and falls, burns, unintentional poisoning, suicide, and homicide (**Table 1**).

ANATOMICAL AND PHYSIOLOGICAL CHANGES OF PREGNANCY

Knowledge of physiologic and anatomic changes in pregnancy and their clinical impact on symptoms and manifestation of traumatic injuries are important in management (**Table 2**).

- *Cardiovascular*: Cardiac output increases due to increased plasma volume, decreased vascular resistance, and increased maternal heart rate (an additional 10–15 beats/min). The supine positioning of pregnant trauma patient increases the risk of superior vena compression and 20–30% reduction in cardiac output due to gravid uterus particularly in second and third trimesters, particularly during the second and third trimesters (**Figs. 1A** and **B**). Blood pressure is lower than normal (5–15 mm Hg less than usual) in the second trimester, which causes difficulty in diagnosing hypovolemia secondary to bleeding but returns to near-normal levels at term.
- *Respiratory*: The airway diameter decreases due to laryngeal edema and increased mucosal congestion, rendering airway management more challenging. Rapid-sequence intubation medications are considered safe. The oxygen consumption is increased and the fetus is very sensitive to hypoxia. For this reason, it is important to keep oxygen saturation above 95%. Functional residual capacity decreases and hyperventilation leads to respiratory alkalosis due to increased pressure on the diaphragm in late pregnancy. Therefore, patients are expected to be hypocapnic [partial pressure of carbon dioxide ($PaCO_2$) ~30 mm Hg] during late pregnancy periods. A $PaCO_2$ closer to 40 mm Hg (the normal value in a nonpregnant patient) should alert the physician of impending respiratory failure.

TABLE 1: Prevalence of types of trauma mechanism in pregnancy.

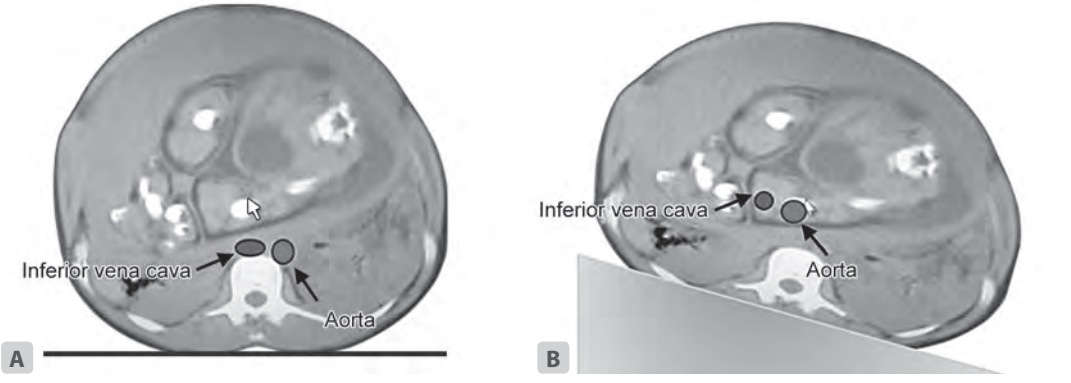
Domestic violence	8.307/100,000 live births
Motor vehicle collision	207/100,000 live births
Falls and slips	48.9/100,000 live births
Toxic exposure	25.8/100,000 person-years
Penetrating trauma	3.27/100,000 live births
Homicide	2.9/100,000 live births
Suicide	2/100,000 live births
Burns	0.17/100,000 person-years

Source: Mendez-Figueroa. Trauma in pregnancy. Am J Obstet Gynecol. 2013;209(1):1-10.

TABLE 2: Anatomic and physiologic changes in pregnancy.

Anatomic changes	*Clinical relevance*	*Physiological changes*	*Clinical relevance*
Edematous and friable airway	Difficult airway, may require smaller ETT	Increase in oxygen consumption	Require high-flow oxygen
Uterus extent beyond bony pelvis after 12 weeks, gravid uterus after 20 weeks	• Direct injury to the uterus • Supine hypotension due to compression of inferior vena cava	• Increase in plasma volume • Increase heart rate/low blood pressure	• Delay in the identification of shock • Poor marker of hemodynamic stability
Bladder moves superiorly	Direct bladder injury	Increase in the bladder and uterine blood flow	Increase in bleeding risk with direct injury
The diaphragm moves upward 4 cm	Pneumothorax, tension pneumothorax, tube placement 2–3 spaces upward	• Increase in renal plasma blood flow and GFR • Increase bicarbonate excretion	• Precaution with drugs which excrete through the renal system • Susceptible to acidosis
Small bowel moves up	Direct blunt/penetrating bowel injury	Decrease in platelets, PT, PTT increase in fibrinogen, d-dimer	Precipitates disseminated intravascular coagulation (DIC) early
Peritoneum-abdominal wall stretches with the progression of pregnancy	Poor assessment of organ injury intra-abdominal bleeding	Other hematopoietic changes in pregnancy are decrease in hemoglobin, hematocrit, and platelets, increase in white blood cell count, fibrinogen factors VIII and X	Awareness about these changes helps in resuscitation and anticipation of various complications

(ETT: endotracheal tube; GFR: glomerular filtration rate; PT: prothrombin time; PTT: partial thromboplastin time)



FIGS. 1A AND B: (A) Compression of the vena cava inferior in the supine position of the pregnant patient and (B) the disappearance of the compression with a tilt of about 15–30° on the right side.

Courtesy: Dr Fatma Sinem Samim.

Rates of hemothorax (Htx) and pneumothorax (Pnx) are unchanged.

- *Gastrointestinal*: Decreased lower esophageal sphincter tone from the effect of progesterone combined with increased intra-abdominal pressure can lead to esophageal reflux and aspiration. Because the uterus displaces the bowels cephalad and laterally in later gestational periods, it can interfere with the abdominal examination and clinical findings, particularly with upper abdomen penetrating injuries.
- *Hematologic*: The volume of plasma increases more than the increase in the number of red blood cells causing physiologic anemia. A mild leukocytosis and relative thrombocytopenia can develop. Coagulation factors [VII, VIII, IX, XII, fibrinogen, and von Willebrand factor (vWF)] increase from the effect of estrogen, and this is thought to increase physiologically to prevent excessive bleeding at delivery, although it may predispose to hypercoagulability during pregnancy.
- *Renal*: Renal plasma flow and glomerular filtration rate increase due to systemic vasodilation and increased cardiac output while blood urea nitrogen and creatinine levels decrease during pregnancy. Proteinuria may increase but levels >300 mg/dL are pathological, requiring consideration of possible preeclampsia. Hematuria is always pathological. Mild dilutional hyponatremia (130–135 mEq/L) can be observed.
- *Reproductive*: Because of its anterior position and size, the uterus is the most frequently injured organ in blunt abdominal trauma. Penetrating injuries to the uterus

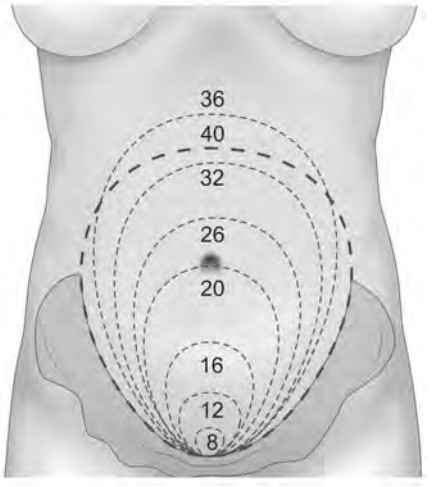


FIG. 2: Estimated pregnancy week based on fundal height.

Courtesy: Clinical Multimedia Unit, Metro North Hospital and Health Service, Queensland.

often result in fetal loss. Fundus height, tenderness, and shape and tone of the uterus must be evaluated. The uterus remains intrapelvic up to 12 weeks of pregnancy, then enters the abdomen, and reaches the umbilicus by 20 weeks and the costal margin (xiphisternum) by 34–36 weeks (**Fig. 2**). In case of decreased maternal blood flow, uterine blood flow decreases, and uterine vasoconstriction occurs. The whole blood volume of the mother passes through the uterus every 10 minutes. During maternal shock, blood flow is preferentially redirected to the maternal central circulation away from the maternal periphery and the uterus. This can lead to fetal distress while the mother remains in compensated shock with no obvious vital sign derangement, underscoring the need for fetal monitoring.

CLINICAL PRESENTATION

- *Blunt trauma* is the most common cause of injury, most often due to domestic violence and MVC. While the abdominal wall and uterus act as a buffer to protect the fetus, complications can include uterine rupture, uterine contractions, premature delivery, placental abruption (the most common cause of fetal loss from blunt trauma), fetomaternal hemorrhage (FMH), and direct fetal injury.
- *Penetrating injury* carries a higher risk of fetal mortality than blunt trauma. The trajectory of the wound must be examined via entrance–exit holes for the possibility of visceral organ injuries. Most stab wounds require extensive exploration.
- *Domestic violence* is the most common type of trauma in pregnant women (8,307/100,000 live births). Domestic violence should be considered with any injury in pregnant women. Risk factors include abuse, young age, poverty, level of education, unwanted pregnancy, and ethnicity. It is important to educate those who provide health services to pregnant women to detect and treat domestic violence. Each emergency department should have a written protocol for sexual abuse assessment.
- *Burns* are rare and the exact incidence is unknown. In severe burns, the mother and fetus are at risk for insensible fluid loss, hypoxia, and sepsis. In case of burns over 60% of the mother's total body surface area, fetal mortality is over 50%. In this case, the caesarean section should be considered as soon as possible.
- *Falls*: One in four pregnant women falls at least once during pregnancy. With the progression of pregnancy, the increased joint elasticity and weight gained in pregnancy may contribute to balance problems. Falls occur more often in the third trimester. Apart from minor lower extremity injuries, preterm labor, placental abruption, fetal distress, fetal hypoxia, uterine rupture, or even fetal death in pregnant women can occur.

EVALUATION

In the management of the pregnant trauma patient, the priority must be on the mother. Evaluation and management are guided by the severity of the trauma and influenced by the gestational age. Fetal evaluation should be done after the primary survey of the mother is completed. Conditions such as placental abruption, fetal trauma, fetal-maternal hemorrhage, Rh (rhesus) isoimmunization, and preterm labor should be evaluated while considering the physiological and anatomical changes in pregnant women. Employing a multidisciplinary approach that includes a trauma surgeon, obstetrician, and neonatologist may be beneficial.

Primary Survey

Every woman of childbearing age should be considered pregnant until proven otherwise. For pregnant patients after trauma, like other patients, ventilation and oxygenation should be optimized after the airway is secured, the bleeding focus should be controlled, and adequate circulation should be restored or maintained.

Airway: Laryngeal edema, mucosal congestion, decreased airway diameter, decreased residual capacity secondary to diaphragm compression, and decreased lower esophageal sphincter tone increasing the risk of aspiration may cause difficulty in airway management, especially after 20 weeks of gestation. In a study by McKeen, 5.7% of intubations were considered difficult. If intubation is pursued, it should be performed by an experienced person and a smaller sized endotracheal tube is preferred in anticipation of airway edema. Alternative airway techniques should be performed after two unsuccessful attempts. As with all trauma patients, it is important to protect the cervical spine if there is a concern for a possible spinal injury.

Breathing: Oxygen saturation should be kept above 95%. Chest tube insertion should be above 1–2 intercostal space higher than the typical fifth intercostal space due to diaphragm elevation during pregnancy.

Circulation: Two veins should be cannulated with a large caliber (14–16 gauge) catheter preferably cephalad to the diaphragm. Maternal hypotension should be treated aggressively; otherwise, it may cause fetal distress. Vital signs may not change until 15–20% of the total blood volume is lost. If transfusion is necessary, crystalloid fluid and blood products (preferably O negative in an emergency situation) should be given initially. Massive transfusion, if indicated, should be administered in a 1:1:1 (fresh frozen plasma, platelets, and packed red blood cells) ratio.

The use of vasopressors is discouraged in resuscitation because they reduce fetal blood flow from vasoconstriction of uteroplacental vasculature. Vasopressors should only be used if there is a transient need to stabilize blood pressure during volume resuscitation. The uterus should be positioned to the left side either manually or by providing a 15–30° tilt to the right side of the patient due to the vena cava vein compression, especially in the second and third trimester; laying in the left lateral recumbent position is also reasonable. *Tranexamic acid* is safe for the fetus in severe bleeding but has not been found to reduce maternal mortality.

In some studies, *viscoelastic assay thromboelastography (TEG)* and *rotational thromboelastometry (ROTEM)* tests have been shown to increase survival for the severely injured patient, provide guidance for blood component transfusion in trauma, and decrease postpartum hemorrhage compared to massive transfusion. Fetal well-being must be evaluated before the secondary survey.

Cardiopulmonary Resuscitation

Pregnant cardiac arrest cases require a multidisciplinary approach. The obstetric and neonatal team should be involved if possible. If the gestational age is over 20 weeks, the uterus should be positioned to the left. Chest compression, ventilation, and defibrillation techniques are unchanged. Cardioversion is considered safe in pregnancy.

Perimortem Cesarean (Resuscitative Hysterotomy)

Perimortem cesarean or resuscitative hysterotomy is a rarely performed yet potentially life-saving procedure in the resuscitation of a pregnant woman and fetus (over 20–24 weeks gestation) in cardiac arrest. Aortocaval pressure from uterine compression begins after the 20th week) potentially disrupting the mother's hemodynamics. If the spontaneous circulation of the pregnant cannot be achieved within 4 minutes, the newborn should be delivered by cesarean section within the next minute (within 5 min of cardiac arrest). Cardiopulmonary resuscitation should be continued without interruption. The chance of spontaneous circulation increases when blood flow is redistributed centrally to the mother away from the uterus. Therefore, early resuscitative hysterotomy is recommended to increase survival for both mother and fetus.

Secondary Survey

Once the patient is stabilized, the head-toe secondary survey should be conducted. Use of a seat belt (directly over the abdomen? no restraints?) should be asked. *C*omplications of pregnancy, *o*bstetric history, *d*ating method and estimated due date, and *e*vent details (e.g., bleeding, fetal movement) (*CODE*) should be questioned.

Physical Examination

- *Gestational age* can be assessed using bedside ultrasound (biparietal diameter or femur length), patient history, medical record, or measuring the distance from the symphysis pubis to the top of the fundus *(1 week/cm)*. On bedside ultrasound, a femur length ≥ 4 cm suggests fetal viability (4 cm correlates with 22–24 weeks gestational age).
- *Abdominal examination* can be unreliable in pregnant patients because of changing organ positions and a lower likelihood of exhibiting peritoneal signs because the uterus can stretch the abdominal wall, further distancing sources of inflammation from the peritoneum. Evaluating for uterine tenderness, vaginal bleeding, and contraction frequency can be helpful. Uterine tenderness and rigidity may be a sign of *placental abruption*, or intermittent pain may also be a precursor of possible labor. In the case of *uterine rupture*, fetal parts may be palpated and the uterus may be tender. However, it may not be detected during an abdominal examination.
- *Vaginal examination* can help identify pathologies such as an open pelvic fracture (concomitant vaginal laceration), placental abruption or pelvic fractures (vaginal bleeding), or rupture of membranes (clear fluid). Initially, the vagina should be examined externally (laceration, ecchymosis, etc.). The physician should avoid frequent examinations. The bimanual examination should evaluate for bleeding from the vagina or uterus, injury to the pelvic bone, and amniotic fluid leakage. Caution should be exercised when evaluating pelvic bony fractures to avoid harm to the examiner. To prevent massive exsanguination, pelvic examination after 20 weeks' gestation should not occur prior to ruling out placenta previa by ultrasound.

Fetal Assessment

Gestational age should be estimated because preterm births under 23 weeks will most likely result in fetal death or severe neurocognitive delays. Presumed viability is generally considered ≥24 weeks. Fetal heart rate (FHR) is important for assessing fetal well-being and the adequacy of maternal blood flow. Abnormal FHRs can occur with maternal hypotension or compensated maternal shock, maternal hypoxia, placental abruption, uterine rupture, or direct fetal injury. It is sufficient to document the FHR before 23 weeks of gestational age. Continuous FHR monitoring and uterine contraction monitoring should be performed in pregnancies 23 weeks onward for at least 4 hours. It is important to recognize that fetal distress may be the first and only presenting sign of material distress.

INVESTIGATIONS

Laboratory Tests

Laboratory tests for pregnant patients are similar to those of other trauma patients and include coagulation studies and type and screen (which evaluates Rh status). All at-risk pregnant women should be given Rh-negative 300 μg anti-D Ig (which protects against 30 mL fetomaternal hemorrhage) within 72 hours. If the mother is Rh-negative, the *Kleihauer–Betke (KB) test* may be performed to determine the amount of FMH and correct dose of Rh immunoglobulin (IG) (in rare cases, the patient may require >300 μg of Rh IG).

Diagnostic Imaging

- *Ultrasound* is inexpensive, reproducible, easily performed at bed side with no radiation exposure to mother or fetus. Ultrasound can be useful in detecting intraperitoneal bleeding after trauma using the FAST (focused assessment with sonography for trauma) exam. It allows evaluation of FHR (normal 110–160 bpm), gestational age, placenta location (previa?), placenta abruption (sensitivity: 24%; specificity: 96–100%), and fetus presentation as well

(cephalad, breech). Ultrasound does not reliably rule out placenta abruption. The use of ultrasound (abnormal FAST exam) may obviate the need for diagnostic peritoneal lavage or the harmful ionizing radiation from computed tomography (CT).

- *Computed tomography*: While the biggest concern is the radiation exposure to the fetus, in the setting of trauma, CT should not be delayed for this reason. Many guidelines report that <50 mGy is not associated with any fetal loss or abnormality during pregnancy although it may cause a 2% increased risk of cancer in the fetus. CT can be used to detect complicated bone fractures, organ and vascular injuries, and placenta abruption which are difficult to detect with ultrasound. The use of contrast is not contraindicated for either mother or fetus. Like ultrasound, limitations of CT include missing diaphragm and hollow viscous injuries. However, unlike ultrasound, a CT scan can identify specific organ injuries and can identify pathology in the retroperitoneum and pelvis.

Magnetic resonance does not cause radiation exposure and may be preferred in case of placenta abruption and evaluation of intrauterine pathologies in stable patients, but its use is limited because of availability and the time required to obtain study away from the emergency department.

PREGNANT PATIENTS NEEDING FETAL MONITORING

Trauma is common in pregnancy. Maternal injuries are mostly due to falls, assaults, and road traffic accident. Fetal death is more frequent than maternal death due to trauma. Observing the pregnant patient in emergency and fatal monitoring is beneficial. A multidisciplinary team in the observation unit is required to care for the mother as well as the fetus. The initial findings due to trauma may be detected within 2 hours or may require admission for prolonged observation. During observation, any vaginal bleeding uterine tenderness or contractions should be noted. These findings may adversely affect the pregnancy. Fetal death after trauma is mostly due to placental abruption.

Cardiotocographic Monitoring

Cardiotocographic monitoring (CTM) should be started soon after trauma to a pregnant woman. Even after minor injuries to the mother, CTM should be initiated as soon as possible. Any changes in the fetal physiology should be noted. The American College of Obstetricians and Gynecologists and Eastern Association for the Surgery of Trauma (EAST) guidelines recommend CTM in all pregnant women greater than 20-week gestation who suffer trauma. CTM should be for a minimum of 6 hours. Monitoring parameters should include FHR, vaginal bleeding, uterine tenderness, significant maternal injury, or rupture of the amniotic membranes. Initially, a patient's CTM should be done for 4–6 hours; if no maternal obstetric symptoms have developed and CTM is reassuring, traumatic complications to the fetus can be ruled out with high sensitivity. CTM should be extended for 24 hours if nonreassuring, and the following features are noted:

- Significant abdominal pain
- Uterine tenderness
- Vaginal bleeding
- Contraction frequency >1/10 minute (during the first 6 h of monitoring)
- Rupture membrane
- Abnormal FHR pattern
- High-risk mechanism of injury
- Serum fibrinogen < 200 mg/dL.

The FHR monitoring is largely used as a screening tool to indicate when more definitive instigations are required, such as nonstress test or biophysical profile. Normal FHR tracing is associated with a good outcome, but abnormal FHR does not always indicate fetal injury. If CTM findings are nonconclusive, ultrasound can assist in the diagnosis of abruption and evaluate fetal well-being. Fetal ultrasound is helpful in direct visualization of the heartbeat, gestational age, presentation, amniotic fluid volume, placental integrity, biparietal diameter, abdominal circumference, and femur length, allowing gestational age and weight to be estimated, essential for planning if delivery is considered. Factors that should be taken into consideration when deciding to observe an injured pregnant patient are the severity of the injuries, gestational age, and viability of the fetus. Maternal health should always take priority over interventions for the fetus.

SPECIFIC CONDITIONS OF PREGNANCY TRAUMA

- *Uterine rupture* is rarely seen after trauma (0.6%), most often after motor vehicle accidents from pelvic fractures hitting the uterus, and considered in the case of abdominal pain, vaginal bleeding, fetal death or abnormality in the FHR, palpation of the fetal parts, or maternal shock. The treatment is primary closure of the laceration or laparotomy depending on severity.
- *Placental abruption* involves disruption of the placenta from the uterus. It is the leading cause of fetal death after trauma. Because placental abruption can occur from deceleration injuries, it may occur in the absence of signs of physical trauma to the abdominal wall. Placental abruption is a clinical diagnosis, not dependent on ultrasound findings, and should be suspected in pregnant women with vaginal bleeding, tenderness in the uterus and abdomen after abdominal trauma, or nonreassuring fetal heart monitoring which is the most sensitive predictor. Vaginal bleeding may not be present. Placental abruption can result in leakage of thromboplastin into the maternal circulation leading to disseminated intravascular coagulation.
- *Preterm labor* refers to delivery before 37 weeks. Preterm labor should be considered in case of symptoms such as four uterine contractions per hour with cervical changes, cramp-like abdominal pain, pressure sensation in the pelvic area, and vaginal bleeding.
  - *Antenatal steroids* are recommended in pregnant women with gestational age of 34 weeks up to 36 weeks 6 days with preterm labor risk or rupture of membranes to accelerate fetal lung maturation.
  - *Tetanus-diphtheria-acellular pertussis (Tdap)* is not contraindicated in pregnancy.

SUMMARY

Management of trauma in pregnancy needs awareness of anatomic and physiologic changes. A team of relevant specialists is required with exceptional coordination. The salient points of management are described below and shown in **Flowchart 1**.

- Anatomic and physiologic changes develop during pregnancy.
- The most common causes of trauma are domestic violence and MVC. Domestic violence should always be considered in pregnancy.
- All patients of childbearing age should be considered pregnant until proven otherwise and managed accordingly.
- The priority is to stabilize the mother. Consultation with obstetrician and neonatologist is recommended.
- Aspiration risk is higher in pregnant women. Edematous mucous membranes can make airway management challenging. The insertion of a nasogastric/orogastric tube should be considered for unconscious patients in the absence of contraindications.
- Oxygen saturation should be maintained >95%.
- If indicated, chest tube insertion should be at the third or fourth intercostal space.
- The uterus should be shifted to the left to prevent compression on the inferior vena cava in pregnancies >20 weeks.
- In patients with gestational age ≥23 weeks, after stabilization, the FHR should be evaluated and monitored for at least 4 hours with obstetrician consultation in case of uterine tenderness and abnormalities in contractions, abdominal pain, vaginal bleeding, rupture of amniotic membrane, abnormality of FHR, or high-velocity trauma.
- In pregnant trauma patients with concern for injury, a CT scan should not be postponed for concern of fetus radiation exposure.
- If the spontaneous return of circulation cannot be achieved within 4 minutes and if the estimated gestational age is ≥20–24 weeks, the perimortem cesarean section should be performed within 5 minutes of arrest.
- Anti-D IG should be given to all Rh-negative pregnant trauma patients.
- Tetanus prophylaxis should be updated, if indicated.

Assessment of maternal status

Stable?
Airway secure? Hemodynamically stable?
Normal mental status?

Yes

Follow ATLS algorithm

Major injury

Yes

- Consult OB
- Get history of the patient
- Do physical examination including pelvic
- Estimate gestational age
- ≥ 23 weeks fetal heart monitoring (at least 4 h)
- UC ≥6/h consider admission
- Do imaging and labs tests
- Check the specific injuries (such as preterm labor, uterine rupture, FMH, etc.)
- Consider anti-D immunoglobulin if the patient is Rh negative, tetanus prophylaxis

No

- *Ex*: Bruising, laceration, etc. (ISS:0)
- Assess the fetus
- Can be evaluated without imaging and laboratory tests
- Consider anti-D immunoglobulin if the patient is Rh negative and tetanus prophylaxis

Admission Criteria
- Vaginal bleeding
- Hypovolemia
- Abdomen tenderness, pain or cramping
- Uterine tenderness
- Abnormality of fetal heart rate
- Leaking of amniotic fluid

No

Start Advanced Trauma Life Support
- Airway-cervical protection
- Breathing ... Maintain >95% ... insert chest tube into the 3rd-4th intercostal space if Ptx or Htx
- Circulation-bleeding control—manually displace the uterus
- Disability
- Exposure
- Call trauma team, OB, neonatologist as soon as possible
- IV access (two lines with 14–16 gauge), give IL lactated ringers, Rh negative blood product, if needed
- Early MTP activation, if needed
- FAST examination
- If >23 week + no ROSC within 4 minutes, PMCD during CPR
- After stabilization check the fetus viability

Secondary Survey
- Assess all injuries in detail
- Detemine gestational age
  >23 week continue fetal heart rate and uterine contraction monitoring (if the patient stable and normal CFHR ...4 hours if not admitted to the hospital)
- Perform pelvic examination (for vaginal bleeding, rupture of membranes, cervical dilatation and effacement, fetal presentation...)
- Do the diagnostic tests and treatment without concern about the fetus
- *CODE*: Complication of pregnancy, obstetric history, dating method and estimated due date, event details (e.g., bleeding, movement)
- *Lab*: CBC, coagulation tests, type and match cross, fibrinogen
- Consider anti-D immunoglobulin if the patient is Rh negative, tetanus prophylaxis

(ATLS: advanced trauma life support; CBC: complete blood count; CFHR: continuous fetal heart rate; CPR: cardiopulmonary resuscitation; FAST: focused assessment with sonography for trauma; FMH: fetomaternal hemorrhage; Htx: hemothorax; OB: obstetrician; MTP: massive transfusion protocol; MVC: Motor vehicle collision; PMCD: perimortem cesarean delivery; Ptx: pneumothorax; ROSC: return of spontaneous circulation; UC: uterine contraction)

236
CHAPTER

Basics of Wound Management

Sukhdeep Singh, Aditya Agarwal, Devendra Richhariya

INTRODUCTION

One of the most common problems seen and treated in the emergency department (ED) is traumatic lacerations of the skin. Because of 24-hour access, the ED remains the most reliable place for effective, safe, and clinically competent wound care. Avoidance of infection and esthetically appearing repair are the most desired outcomes by the physician as well as by the patient. A disciplined approach to wound management will improve patient care and satisfaction. This chapter describes the current and fundamental aspects of basic wound management, which include a focused history, methodical physical examination, meticulous wound preparation, effective wound closure techniques, and pertinent postrepair care instructions

What is a Wound?

A wound is a discontinuity and breakage of the normal structure and function of the skin. An acute wound has normal wound physiology and the healing follows the normal stages of wound healing, whereas a chronic wound does not heal in an orderly manner and is physiologically impaired.

CLASSIFICATION OF WOUND

Acute wounds heal as anticipated and proceed through a normal, orderly, and timely reparative process that results in sustained restoration of anatomic and functional integrity. Chronic wounds do not heal as anticipated and fail to proceed through this process or proceed through the process but fail to establish a sustained anatomic and functional result. Chronic wounds may get stuck in any of the phases of wound healing for greater than 6 weeks.

Acute Wounds

Lacerations are usually caused by a simple shearing force (e.g., from a knife or glass). This is a simple dividing of tissue. There is little kinetic energy imparted to the tissue, so the surrounding tissue injury is minimal, although glass injuries can cause significant damage to soft tissues. Partial avulsion lacerations are complicated lacerations in which the dermis has undergone a significant separation from the superficial fascia, creating a "flap of dermis." This wound can compromise the flap of tissue because its remaining blood supply is derived from the intact dermal portion at the base of the flap. In random flaps, clinical experience has resulted in the observation that the ratio of flap length to width is critical for complete flap survival. This rule varies from anatomic site to anatomic site. Tension injuries are a result of a blunt or a semiblunt object striking the skin at an angle. Often a triangular flap is created, and the blood supply is interrupted on two sides of the flap. Crushing or compression injuries occur when a relatively blunt object strikes the skin at a right angle. These lacerations often have ragged or irregular edges, and a significant amount of kinetic energy is transferred to the surrounding and underlying tissue. Shearing force is a mechanical force that is parallel rather than perpendicular to an area. This may cause a triangular-shaped flap or tunneling.

Puncture Wounds

Puncture wounds account for 3– 5% of all traumatic injuries presenting to pediatric emergency rooms. Most are on the plantar aspect of the foot. Puncture wounds are commonly caused by nails but can also occur via envenomation, human and animal bites, iatrogenic causes, and foreign bodies such as wood, metal, glass, and plastic. One must be vigilant to suspect a retained foreign body if the mechanism of injury suggests it.

Bite Wounds

Bite wounds are one of the most common types of trauma. The majority of such wounds are caused by dogs, cats, and humans and often involve young children. The mechanism of injury can frequently cause crushing, tearing, or avulsion of tissue and cause devitalized tissue with significant bacterial contamination.

Abrasions

Abrasions are skin wounds caused by a tangential force to the epidermis and dermis. The skin surface is forced against a resistant surface and essentially scraped away. Varying thicknesses of the epidermis and/or dermis can be lost, and deeper abrasions can occur. Abrasions can cover a significant amount of the total body surface area and are frequently impregnated with grass, asphalt, and dirt.

Burns

A burn is a damage to the skin and underlying structures caused by excessive heat or caustic chemicals. Burns are usually divided into three depths of tissue injury. Superficial or epidermal burns, typified by the common sunburn, are confined to the epidermis. Partial-thickness burns involve the epidermal layer and part of the dermal layer (formerly referred to as second-degree burns). This can further be divided into two depths of partial-thickness burns: superficial partial thickness and deep partial thickness. Superficial partial-thickness burns involve destruction of the epidermis and the upper one third of the dermis. Blisters form in this type of burn. Deep partial-thickness burns destroy the epidermis and most of the dermal layer. As a result, the wound is white and dry. Full-thickness burns are burns in which the epidermis, dermis, and epidermal appendages have been destroyed. This burn is waxy and white. Subdermal burns involve the destruction of the outer epidermis and dermis and extend to the tissue below, including fat, tendon, muscle, and bone. Burn severity is determined by the depth of burn, total body surface area burned in percent, location of the burn, and patient age. The rule of nines is a commonly used tool to divide the surface of the body into segments of 9%. Age is a major factor in determining the prognosis of the burn, with infants and elderly individuals at higher risk for a mortal event. The depth of heat or caustic injury depends upon the quantity of heat exposure and depth of heat penetration. Location of the burn with respect to anatomic function and depth of overlying skin also play a role in the severity of the burn. Initial evaluation of a burn patient in the emergency department may underestimate the severity of the burn. The wound may involve deeper structures than can be estimated upon primary evaluation. Burns are dynamic and can evolve into deeper wounds over time depending upon the initial injury and subsequent environmental insults.

Chronic Wounds

Chronic wounds arise from acute wounding if appropriate interventions are not initiated or if factors known to delay healing predominate. Chronic wounds often occur in individuals who have underlying comorbidities, including advanced age, peripheral vascular disease, malnutrition, diabetes, chronic steroid use, or other chronic diseases that impair tissue healing. Chronic wounds do have differences at the cellular level that distinguish them. Chronic wounds do not have clot formation, which diminishes the growth factors present in platelets and "primes the wound for healing." Debridement can improve healing by exposing viable tissue. Most chronic wounds are colonized with bacteria and thus require more macrophages and immune response to be mounted to clear away debris, contributing to prolonged healing time. Increased epithelialization, which increases scar friability and the need for increased angiogenesis, can also prolong wound healing. Chronic wounds generally have extensive tissue loss and extensive tissue remodeling.

Pressure Ulcers

A pressure ulcer is a disruption of the normal anatomic structure and function of skin that results from an external force associated with a bony prominence that does not heal in an orderly and timely fashion. Pressure ulcers can be categorized according to the National Pressure Ulcer Advisory Panel definitions.

- *Stage 1*: An observable pressure-related alteration of intact skin, with indicators such as an adjacent or opposite area on the body, which may include changes in one or more of the following: skin temperature (warmth or coolness), tissue consistency (firm or boggy feel), or sensation (pain, itching). In lightly pigmented skin, the ulcer appears as a defined area of persistent redness, whereas in darker skin tones, the ulcer may appear with persistent red, blue, or purple hues.
- *Stage 2*: Partial-thickness skin loss involving the epidermis, dermis, or both
- *Stage 3*: Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend down to but not through the underlying fascia
- *Stage 4*: Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures

Diabetic Foot Ulcers

Diabetic foot ulcers typically occur on the plantar aspect of the foot in areas prone to excessive pressure. They generally present as symmetric, round, puncture-appearing wound cavities with a clean wound bed and callous around the wound. The atherosclerotic occlusive disease is a factor in the development of malperforate ulcers; however, the combination of autonomic neuropathy, infection, and autonomic dysfunction, which produces anhidrosis and hyperkeratosis, also contributes to the development of this wound. Diabetic patients typically manifest lesions in the distal popliteal and tibioperoneal arteries, with usual sparing of the dorsal foot.

Venous Insufficiency Ulcer

Venous insufficiency ulcers are typically partial-thickness wounds resulting from chronic venous insufficiency. They are usually located between the mid-calf and malleolus. They have shaggy, irregular borders and often have heavy exudates. There is a brownish pigmentation of the skin secondary to extravasated hemoglobin and loss of subcutaneous fat, leading to lipodermatosclerosis. Although there is a unanimous agreement that venous ulcers are due to venous stasis and back pressure, there is less consensus as to the exact pathophysiology that leads to ulceration and impaired healing.

Ischemic Wounds

Ischemic wounds are generally atrophic and can lead to necrosis of the affected part. The wounds are generally shallow, painful, have a pale base, and are usually caused by a decrement in blood supply to the affected body part. The wounds are commonly present on the most distal portions of the extremities, although more proximal locations are encountered. Other signs of peripheral ischemia, such as dryness of the skin, hair loss, scaling, and pallor, can be present. The occlusive disease is often manifested in the superficial femoral system, often in the adductor hiatus or Hunter's canal. This brief introduction of the anatomy and types of wounds will help in the evaluation of wounds seen in the emergency department. Knowledge of skin structure can help to define the

depth of injury and informs the clinician of the extent of repair that must occur to restore tissue health.

WOUNDS COMMONLY MANAGED IN EMERGENCY

Clean lacerated wound or simple laceration: These are clean-cut wounds with clean margins; no dirt or contamination is present in these wounds. These could be superficial (involving the superficial layers of the skin) or deep (involving all layers of the skin). Simple lacerations may be cleaned and closed primarily with tapes, staples, or sutures (**Fig. 1**).

Complicated laceration: These lacerations involve deeper layers of tissue such as muscle, tendon, joints, nerves, or blood vessels. Complicated lacerations may need cleansing and debridement of the wound. It is not uncommon for the irregular skin edges or skin at sites where such lacerations meet to break down, and therefore plastic surgical techniques may be needed to provide an acceptable cosmetic and functional result (**Fig. 2**).

Contaminated laceration: These may be simple or complicated lacerations that are contaminated with dirt or saliva (bites), foreign bodies, and other contaminants. These wounds have the potential to become infected or result in post-traumatic tattooing (**Fig. 3**).

Large-tissue defect: This can result from traumatic wounds or the need to remove devitalized tissue due to infection (e.g. Fournier's gangrene). Once the debridement is completed, the wound needs special care until the wound bed allows for skin graft or flap closure.

ASSESSMENT OF THE WOUND

After the initial evaluation of vitals, the assessment of lacerations includes determination of time and mechanism of injury, a history of allergies, the status of immunization (tetanus, hepatitis, and others), the extent of the wound, and the presence of a foreign body and the type of injury—simple or complicated (**Table 1**). The parameters given below may impact the plan for wound repair and its final outcomes and must be evaluated carefully prior to initiating the management of the laceration.

Location and time of injury: In the case of head and facial injuries, the healing is relatively independent from the time of injury to the time of repair. They can be closed up to 24 hours later if the injury is reasonably clean. There is no ideal time between injury and time of laceration, but a repair must be attempted at the earliest.

Mechanism of injury: Understanding the mechanism of injury helps to define the type of laceration (simple or complicated), the presence of a foreign body (contaminated), and thus the prognosis for the development of infection or scarring. Injuries such as those caused by compressive trauma may have a component of crush injury and thus have the highest risk of infection. Other considerations include:

- Bite wounds which must be evaluated for associated injuries and risk of infection
- Crush injuries which may involve devitalized tissue that must be debrided to decrease the risk of infection
- Stab wounds which should be evaluated for depth; surgical consultation may be necessary if the underlying structures (e.g., fascia) have been penetrated or damaged.

FIG. 1: Clean lacerated wound on the forehead. ***(For color version, see plate 43)***

FIG. 2: Complicated laceration of the face. ***(For color version, see plate 43)***

FIG. 3: Post-traumatic tattooing due to inadequate removal of foreign bodies. ***(For color version, see plate 44)***

Presence of foreign body: Identifying and removing foreign bodies are important because retained foreign bodies increase the risk of delayed wound healing and infection. Any foreign body that can be easily seen should be removed. If the object can be reliably palpated, the wound should be explored to make an attempt to remove it, provided there is no risk to underlying critical structures. A nonirritant foreign body, such as glass or metal, that is not in a critical area (e.g., a joint space) or adjacent to a vital structure (e.g., major blood vessel) and not causing any ongoing irritation may be left in place if unable to be removed, and the wound sutured. Irritant material, such as wooden splinters, can be a source of later infection and should be removed even if it requires exploration of the base of the wound. Direct wound inspection may fail to detect all foreign bodies, particularly if the base of the wound cannot be seen. Deep wounds, wounds on the head or foot, and wounds due to trauma in a motor vehicle accident or due to glass cut injuries are more likely to contain retained glass. Radiologic evaluation by a plain X-ray is helpful if the foreign body is radiopaque and should be considered as an adjunct to visual inspection if history indicates a possibility of a foreign body or debris (**Figs. 4A** to **C**).

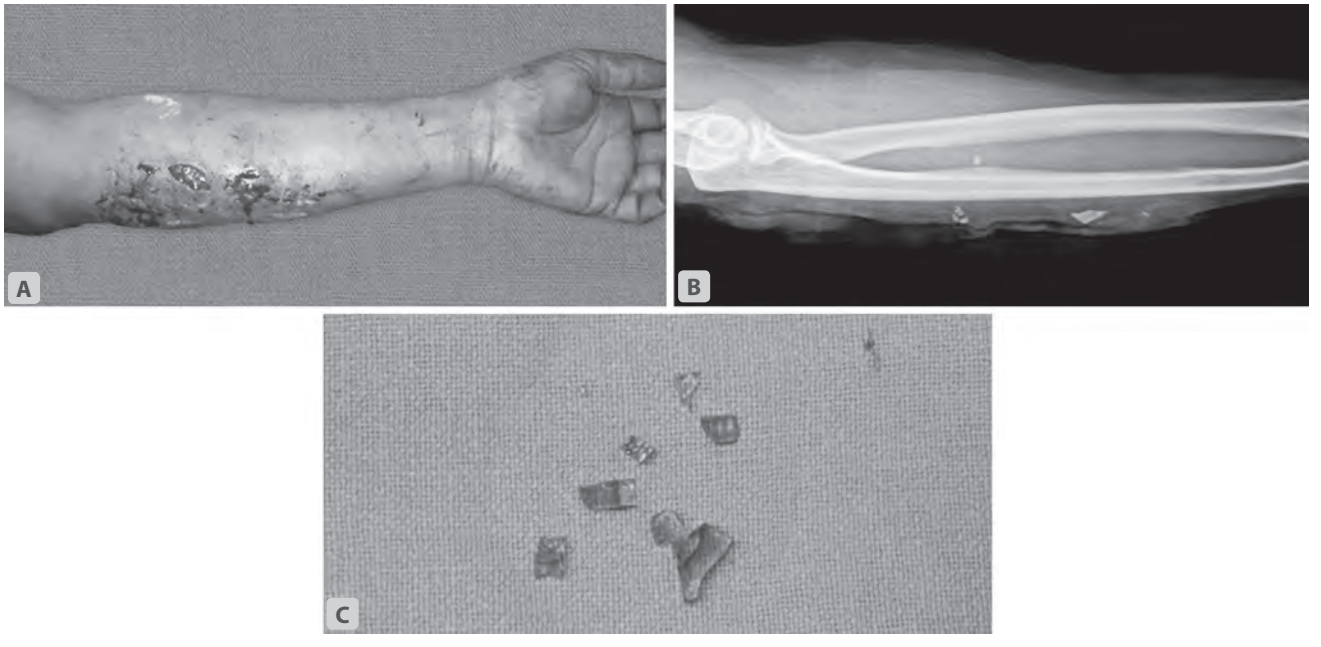
Extent of wound: The base of the wound must be identified whenever possible. Injury to underlying structures, such as a fracture beneath a laceration or penetration of joint space in a finger laceration, has significant implications for management and must therefore be identified.

Neurovascular or tendon injury: Careful assessment of circulation and sensation, including two-point discrimination in hand injuries, will identify the neurovascular injury. Any wound overlying a tendon should be assessed for tendon function and the base of the wound should be carefully explored, with a tourniquet and loupes if necessary, to identify an injured tendon. Tendons must be explored in movement or as the position of the body during the injury, i.e., an injury might be missed if a laceration occurred with the finger in flexion and the wound is inspected only with the digit in extension. Similarly, the ends of a tendon that has been completely severed may retract from view. Wounds that involve joints, nerves, tendons, and major blood vessels require operative exploration.

Investigations: Investigations are needed if there is an underlying deeper tissue injury or nonvisualization of the base of the wound which may need operative exploration. These investigations may include complete blood counts, coagulation profile, viral markers, a plain X-ray, CT scan/MRI scan of the local region to evaluate and exclude fractures, neurovascular injuries, and any foreign body.

TABLE 1: Clinical evaluation of a patient with a laceration

History	*Clinical examination*	*Local examination*
Time of injury	Vitals	Depth of laceration, and extent of the wound
Mechanism of injury	Obesity	Neurovascular or tendon injury
Immunization status for rabies and tetanus	Peripheral arterial disease	Visualization of the base of the laceration
Allergies to antibiotics, anesthetics, latex, and other drugs	Malnutrition	Presence or absence of foreign body
Ongoing medical therapy and concomitant illnesses	Hypertension, chronic renal failure	Special considerations (injury near/to eye, animal bites)
Any implants (for imaging purposes)	Tendency to form keloids	Cosmetic significance of the wound



FIGS. 4A TO C: (A) Patient involved in road traffic accident with multiple cut injuries to the forearm with retained glass pieces; (B) X-ray showing multiple radiopaque shadows suggestive of retained glass particles; (C) Multiple glass pieces removed from the wound. ***(For color version, see plate 44)***

WOUND PREPARATION

The management of lacerated wounds has two primary aims: (1) *A good approximation to give a functional and cosmetically acceptable resultant scar* and (2) *minimizing infection.* Once the patient has been examined and necessary investigations conducted, the next steps include:

Irrigation: It is an important means of minimizing wound infection as it washes out any soil or small foreign bodies that may remain and reduces the bacterial load. However, irrigation is not mandatory and may be avoided in low-risk wounds, especially those in well-vascularized locations. Irrigation should be performed after adequate local anesthesia has been administered or peripheral nerve block has been performed. Consideration must be given to the irrigation solution, pressure, and volume. Isotonic (normal) saline is frequently used for uncomplicated wounds, when easily available; warmed saline may offer a comfort advantage to room-temperature irrigation. Other antiseptic solutions such as chlorhexidine and hydrogen peroxide are no longer used as they may be toxic to wound tissue, impede wound healing, or have other adverse effects.

Hair removal: Hair does not need to be shaved in most cases and is best trimmed to avoid interference with wound closure or knot formation. Lubrication to comb the hair away from wound margins or simple clipping with scissors is all that is necessary in most cases. Shaving flush to the skin level increases the risk of infection. In case of lacerations around the eyebrow, great care must be taken to maintain the hairline of the eyebrow to ensure cosmesis and this hair must not be shaved.

Preoperative antibiotics and immunization: For clean lacerated wounds stitched within the first 6 hours of injury, no oral or injectable antibiotics are needed. In the case of contaminated wounds, broad-spectrum coverage for both gram-positive and gram-negative bacteria should be given.

Tetanus toxoid: Tetanus immunization must be done, especially for patients who have either never been vaccinated (250 U of intramuscular human tetanus immune globulin) or did not have tetanus shots in the last 10 years [intramuscular or subcutaneous tetanus toxoid (0.5 mL)] (**Table 2**).

Rabies: If the laceration is due to the bite of a wild animal, administer rabies prophylaxis. If a domestic animal is the reason, check the rabies immunization status and quarantine the animal for 10 days.

Pain relief: The author suggests the use of local anesthetic agents such as xylocaine to improve patient cooperation and minimize patient discomfort during examination and surgical procedure (**Table 3**). Procedural or conscious sedation should be considered for the repair of wounds in areas that require the patient to be still (e.g., wounds that are near the eye or mouth) or in patients whose inability to cooperate jeopardizes the adequacy of repair (**Table 4**).

TABLE 2: Tetanus prophylaxis in routine wound management (>18 years)

Tetanus immunization	*Clean minor wound*		*All other wounds*	
	Td	*TIG*	*Td*	*TIG*
<3 dose or uncertain	Yes	No	Yes	Yes
>3 dose				
Last dose within 5 years	No	No	No	No
Last dose within 5–10 years	No	No	Yes	No
Last dose >10 years	Yes	No	Yes	No

Note: All other wounds—contaminated wounds (feces, dirt, saliva, soil), puncture wounds, avulsions, burns, crush injuries, and frostbite

(Td: tetanus-diphtheria toxoid; TIG: tetanus immune globulin)

TABLE 3: Agents used for local anesthetic.

Agent	*Onset of action*	*Duration of action*	*Dose*
Lidocaine	Fast	1–2 h	4.5 mg/kg of 1%
Lidocaine with epinephrine	Fast	2–4 h	7 mg/kg of 1%
Bupivacaine	Intermediate	4–8 h	2 mg/kg of 0.25%
Bupivacaine with epinephrine	Intermediate	8–16 h	3 mg/kg of 0.25%
Procaine	Slow	15–45 min	7 mg/kg
Procaine with epinephrine	Slow	30–60 min	9 mg/kg

TABLE 4: Agents for procedural sedation.

Medication	*Dose*	*Route*
Fentanyl	1–2 µg/kg	Intravenous
Midazolam	0.02–0.1 mg/kg (adult); 0.05–0.15 mg/kg (child)	Intravenous
Ketamine	1–2 mg/kg (IV); 2–4 mg/kg (IM)	Intravenous/ intramuscular
Propofol	1 mg/kg	Intravenous
Etomidate	0.1–0.2 mg/kg	Intravenous

MATERIALS USED FOR CLOSURE OF LACERATIONS

Sutures

Sutures may be monofilamentous (Prolene or Ethilon) or multifilamentous (silk). The designation for suture strength is the number of zeros. The higher the number of zeros (1-0 to 10-0), the smaller the size and the lower the strength. They can also be defined as absorbable (dissolve within 14–180 days) or nonabsorbable. Types of suture material used in laceration are summarized in **Table 5**.

Staples

Staples can be used best in clean lacerated wounds of the scalp, trunk, arms, and legs, especially in a mass causality situation. They are best avoided on the face or the neck due to poor approximation of the edges and thus poorer cosmetic

TABLE 5: Choosing appropriate suture material for body region and their removal.

Body part	*Suture material (skin)*	*Suture material (deep)*	*Closure*	*Suture removal*
Scalp	3-0 or 4-0 NA	4-0 SA	Single tight layer	7–12 d
Ear	6-0 NA	5-0 SA	Interrupted	4–6 d
Eyebrow	6-0 NA	4-0 or 5-0 SA	Layered closure	4–6 d
Eyelid	6-0 NA	–	Single-layer horizontal mattress	4–6 d
Lip	6-0 NA	4-0 silk/SA (mucosa)	Three-layer closure	4–6 d
Oral cavity	–	4-0 SA	Layered closure if tongue muscles are involved	7–8 d
Face	6-0 NA	4-0 or 5-0 SA	Layered closure if full-thickness laceration	4–6
Neck	5-0 NA	4-0 SA (subcutaneous)	Two-layer closure for best cosmetic results	4–6
Trunk	4-0 or 5-0 NA	4-0 SA (subcutaneous)	Single or layered closure	7–12
Extremities	4-0 or 5-0 NA	3-0 or 4-0	Splint if wound over the joint	7–12
Hand and Feet	4-0 or 5-0 NA	–	Only skin closure	7–12
Nailbed	5-0 SA	–	Replace nail until the cuticle	Allow to dissolve

[NA: nonabsorbable suture (nylon, polypropylene); SA: synthetic absorbable suture]

results. In patients who may need computed tomography or magnetic resonance imaging as part of their care, staples are best avoided for scan artifacts and possible avulsion by the powerful magnetic field.

Many stapling devices are commercially available. Units that hold between 5 and 25 staples can be purchased. The 10-staple unit suffices for most lacerations. The stapling is done after approximation of the adjacent skin margins with eversion of the skin edges using toothed forceps (forceps with teeth) or the thumb and forefinger. The stapler is placed firmly on the skin without indenting it, aligned with the center of the wound, and gently squeezed to eject the staple onto the skin, ensuring proper apposition of the wound margins. Staples can be removed within 5–7 days by positioning the staple remover under the staple and depressing its handle to ease the staple out of the skin.

Tissue Adhesives (Cyanoacrylates) and Tapes

Cyanoacrylate tissue adhesives are liquid monomers that upon exposure to moisture (e.g., on the skin surface) change to polymers that form a strong tissue bond.When applied to a laceration, the polymer binds the wound edges together and permits normal healing of the underlying tissue.

Once applied, the maximum bonding strength is achieved within 2 minutes of application. The tissue adhesives form a barrier to moisture and microbes over the wound with longer side chain adhesives taking longer to set. The bonded adhesives spontaneously slough off within 5–10 days. Compared with wounds closed with either absorbable or nonabsorbable sutures, the tensile strength of wounds closed by tissue adhesives is less at the time of initial application but equalizes by 1 week after repair.

We suggest that patients with short (<5 cm) traumatic skin lacerations that are clean have good wound approximation, are under low wound tension, and undergo repair with tissue adhesives rather than sutures. Clinical experience indicates that scalp wounds can also be closed with tissue adhesive, but the hair around the wound needs to be trimmed prior to closure. Adhesives are also helpful for closure of skin tears and flaps in patients with fragile skin that cannot be easily sutured (e.g., elderly patients). When wounds are under tension, the placement of subcutaneous sutures can often reduce the tension sufficiently to permit the use of tissue adhesives for skin closure.

Tissue adhesives have the following advantages for the repair of short, clean, straight, traumatic lacerations with low wound tension when compared with sutures:

- Less painful procedure
- More rapid repair time
- Creation of a waterproof and antimicrobial barrier
- Better acceptance by patients
- No need for suture removal or follow-up
- Cosmetically similar results at 12 months postrepair

Evidence suggests that wound dehiscence occurs more frequently with tissue adhesives but that the frequency of dehiscence in properly selected wounds is low (baseline frequency 4%). Tissue adhesives are not thought to prevent the formation of keloids but may promote less tissue reaction than sutures when performing closure of small lacerations in susceptible patients.

Tissue adhesives should not be used in:

- Wounds under tension, unless subcutaneous sutures can be placed to lessen tension and permit good wound approximation
- Complex stellate lesions, crush wounds, or other lacerations with poor wound approximation
- Wounds on the hands, feet, or over joints unless the affected areas are immobilized because repetitive movements could cause the adhesive bond to break before sufficient tensile strength is achieved
- Oral mucosa or other mucosal surfaces (e.g., vagina) or areas of high moisture, such as the axillae and perineum
- Wounds in hairy areas unless the hair is trimmed
- Wounds requiring a high level of precision (e.g., hairline or vermilion border)

- Bite wounds and other wounds at increased risk of infection (e.g., puncture wounds, wounds with devitalized or contaminated tissue).
- Allergy to adhesives (or formaldehyde)

Caution should be used when applying them to wounds in conditions that may delay wound healing such as diabetes mellitus, chronic vascular disease, peripheral vascular disease, decubitus ulcers, and prolonged steroid use.

Ocular exposure to cyanoacrylates: The eyes should be well protected during the repair of adjacent lacerations. If adhesive gets into the eye, under the eyelid, or glues the eyelashes together, generous amounts of ophthalmic antibiotic ointment should be placed within the eye and on the eyelid to break down the adhesive. Gentle manual traction typically permits the reopening of eyelids that have been glued shut. If manual traction is unsuccessful, an ophthalmologist should be consulted. Once the eyelids are reopened, the patient should be assessed for a corneal abrasion.

Surgical tapes, such as "*steri-strips*," may be used directly in the case of small clean superficial lacerations and in areas of low skin tension, and are a useful alternative to staples. However, tape alone is usually not effective and should be used in conjunction with adhesives, such as tincture of benzoin. Unfortunately, local skin reaction occurs due to tincture of benzoin. Surgical tape is typically placed perpendicular to the wound and in strips parallel to each other. It has been noted, however, that in certain wounds on the back and chest, this method can lead to blistering secondary to an increased shearing effect of the surgical tape. Blistering was not present when the surgical tape was placed parallel to the wound edges on wounds in the same anatomical locations. The tape should be left in place until it falls off. Disadvantages with this method of closure include the inability to place the tape on areas with significant hair as well as the inability of the patients to get them wet. Tissue adhesive steri-strips are useful for facial lacerations in the pediatric population as per recent studies.

TYPES OF WOUND CLOSURE

Wound closure can be divided into three types: *primary*, *secondary*, and *delayed.* When the wound closure is done before the formation of granulation tissue, it is known as *primary closure*. This is generally done in all clean wounds but not in the puncture wound because this wound cannot be irrigated adequately. Contaminated wounds, noncosmetic animal bites, abscess cavities, and wounds presenting after a delay should be irrigated, hemorrhage controlled, and debrided. When the wound closure is performed after 3–5 days, it is termed *delayed primary closure.* This allows the patient's defense system to decrease the bacterial load. The bacterial load will be at its lowest approximately 96 hours after the time of initial impact. Secondary closure is healing by granulation tissue. Partial-thickness avulsions (i.e., fingertip injuries), contaminated small wounds (i.e., puncture wounds, stab wounds), and infected wounds closure is done by *secondary closure*.

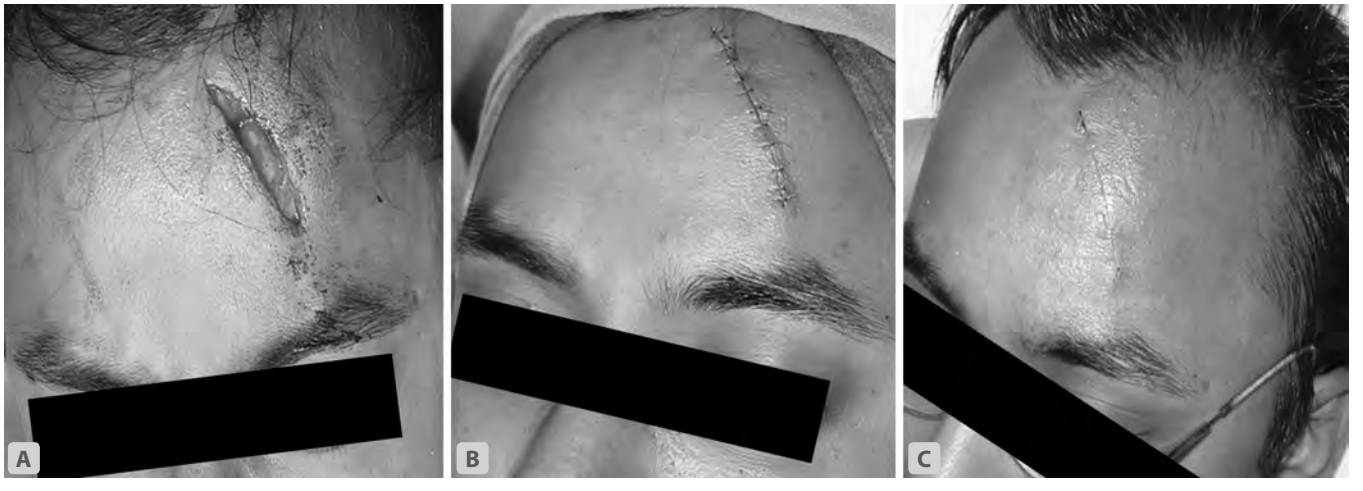
WOUND CLOSURE

Clean lacerated wounds: *Primary closure*—clean lacerated wounds may undergo primary closure at the earliest any time up to 12–18 hours after injury; location on the trunk or proximal extremity and the patient's lack of other risk factors favor success in closure. The wounds of the head and neck have rich vascularity and may be primarily closed up to 24 hours postinjury (**Figs. 5A** to **C**).

Contaminated or complicated lacerations: *Primary closure* is done only in the case of a noncontaminated injury that is recent in origin (<12–18 hours) Absolute contraindications to a primary wound closure are signs of inflammation (redness, warmth, swelling, pain). In the absence of these findings, the decision to suture is based upon clinical judgment. *Closure by secondary intention*: Indications for secondary closure (i.e., by granulation and wound contraction) include:

- Deep stab or puncture wounds that cannot be adequately irrigated
- Contaminated wounds
- Small noncosmetic animal bites
- Abscess cavities
- Presentation after a significant delay (i.e., >24 hours)

Delayed primary closure: This is considered for uncomplicated wounds that present after the safe period for primary closure. It involves initial cleaning and debridement followed by at least a 4- to 5-day waiting period. Consideration of the relationship of the laceration to the relaxed/resting skin tension lines (RSTL) is essential. Lacerations that are oblique or perpendicular to



FIGS. 5A TO C: (A) Clean lacerated wound of the forehead; (B) Primary closure of the wound; (C) Postoperative results after 4 weeks. ***(For color version, see plate 44)***

these lines are at an increased risk of scarring. Therefore, any excision should be parallel to the RSTL. A jagged laceration in which some of the components are parallel to the RSTL may result in a better cosmetic repair than a wound that has been excised.

Technique of wound closure and cosmetic concern: The major consideration while selecting the technique of wound closure is scarring (cosmetic concern). When the goal is to obtain the best function, the laceration should be closed in a single layer with the least number of sutures. When cosmetic is the most important concern, a multiple-layer closure should be used. **Table 6** summarizes the wound factors associated with cosmetic concerns. All wound heals with the scar, but patient factors, wound factors, and technical factors influence the final appearance of scar. Wound factors include the nature of the wound (elective or traumatic), location and orientation of the wound, vascularity of the tissues, elasticity and tension of soft tissues, and degree of contamination. Technical factors include the handling of tissues, debridement, sutures used, and method of wound repair. Avoiding rough tissue handling and the use of crushing instruments are important in preventing tissue ischemia, which leads to necrosis and poor scarring.

TABLE 6: Factors contributing to scar visibility.

Factors associated with scarring	*Measure to minimize scarring while closure*
Direction of wound perpendicular to lines of static and dynamic tension	Layered closure; proper direction in elective incisions
Wounds infection requiring removal of sutures and healing by secondary intention	Proper wound preparation; irrigation and use of delayed closure in contaminated wounds
Wide scar secondary to tension	Layered closure, proper splinting, and elevation
Suture marks	Remove all percutaneous sutures within 7 days
Uneven wound edges	Careful, even approximation of wound superficial layer to prevent differential swelling of edges
Inversion of wound edges	Proper placement of simple sutures or use of horizontal mattress sutures
Tattooing secondary to retained dirt or foreign body	Proper wound preparation and debridement
Tissue necrosis	Use of corner sutures on flaps, splinting, and elevation of wounds with marginal circulation or venous return; excision of nonviable wound edges before closure
Compromised healing secondary to hematoma	Use of properly conforming dressing and splints
Hyperpigmentation of scar or abraded skin	Use of sun block with a sun protection factor R15 for 6 months
Superimposition of blood clots between healing wound edges	Proper hemostasis and closure; proper application of compressive dressings
Failure to align anatomic structures (e.g., vermilion border) properly	Meticulous closure and alignment: use of regional blocks

ANTIBIOTICS IN WOUND CARE

The use of prophylactic antibiotics in wound care is controversial. Various studies do not show any benefits of using prophylactic antibiotics in a simple laceration. Evidence supports the use of antibiotics in hand injuries involving fractures, contaminated wounds, crush injuries, animal bites, and human bites. In dog bite wounds, debridement is more effective than prophylactic antibiotics in reducing infection. Prophylactic antibiotics are beneficial in puncture wound as it could not be irrigated thoroughly and chances of infection are higher. In general, antibiotics are recommended for contaminated wounds or wounds that cannot be adequately debrided or irrigated. Also, antibiotics need to be considered in patients who are more prone to infection including diabetics. Each wound needs to be considered individually, and the patient should have good follow-up, especially when the clinician decides not to provide antibiotics in potentially high-risk wounds (**Table 7**).

Indications of antibiotic prophylaxis following dog bites wounds are as follows:

- Hand wounds
- Deep puncture wounds
- Wounds requiring surgical debridement
- Wounds in older patients
- Wounds in immunocompromised patients
- Bite wound near or in a prosthetic joint
- Bite wound in an extremity with underlying venous and/or lymphatic compromise

AFTER-CARE INSTRUCTION

If possible, wounds should be covered with a nonadherent dressing for 24–48 hours. This period allows enough epithelialization to protect the wound from contamination. Compression dressings should be applied to wounds with the potential for hematoma formation. This dressing is left in place for 24– 48 hours. After this time period, dressings should be removed, and wounds should be cleaned three to four times a day to minimize coagulum between wound edges. Thereafter, patients should be advised to administer a sun-blocking agent with a sun protective factor of 15 to the wound to prevent hyperpigmentation from exposure to sunlight. This process should be continued for 6 months. Tissue adhesives do not require removal and will slough off over 5–10 days with wound epithelialization. Sutures and staples require removal on an average of 7 days after placement. Facial sutures can be removed in 3–5 days to avoid the formation of sinus tracts.

TABLE 7: Antibiotic prophylaxis and therapy—post-wound care.

Conditions		*Antibiotic recommendation*
Open fracture wounds	Types I and II fracture wound (adult)	First-generation cephalosporin, cefazolin 1–2-g IV 8 hourly (for 24 hours after wound closure)
	Type III fracture wound (adult)	First-generation cephalosporin + Gentamycin (1.5–3 mg/kg IV 8–12 hourly) (continue after 72 hours after wound closure)
	Farmyard injury (fecal, clostridial contamination)	Add high-dose penicillin
Human bite	High risk and hand bite	First-dose IV ampicillin-sulbactam or cefoxitin 1 g, then oral antibiotic amoxycillin-clavulanate for 5 days (if the first dose of injectable antibiotic is not possible, continue amoxycillin-clavulanate for 5 days)
	Infected human bite	First-dose IV ampicillin-sulbactam (3 g IV 6 hourly) or cefoxitin 1 g IV 8 hourly or ertapenem 1 g/d followed by amoxycillin-clavulanate (875 + 125) orally 12 hourly—continue for 5 days
Dog/cat bite	High-risk dog bite/all cat bite	First-dose IV ampicillin sulbactam (3 g IV 6 hourly) or imipenem (meropenem 1 g IV) followed by amoxycillin-clavulanate (875 + 125) orally 12 hourly—continue for 5 days
	Infected bite	First-dose IV ampicillin-sulbactam (3 g IV 6 hourly) or cefoxitin 1g IV or piperacillin-tazobactam 3.375 g IV followed by amoxycillin-clavulanate (875 + 125) orally 12 hourly—continue for 5 days
Plantar puncture wound		Ciprofloxacin
Underlying immunocompromised status (HIV, uncontrolled diabetes, chronic steroid use)		Amoxycillin-clavulanate or second-generation cephalosporin
Alters local defense (peripheral arterial disease)		Amoxycillin-clavulanate

- Alternative antimicrobial recommendations: Clindamycin/clindamycin fluroquinolones
- If first parenteral antibiotic therapy is not possible, then continue amoxycillin-clavulanate for 5 days

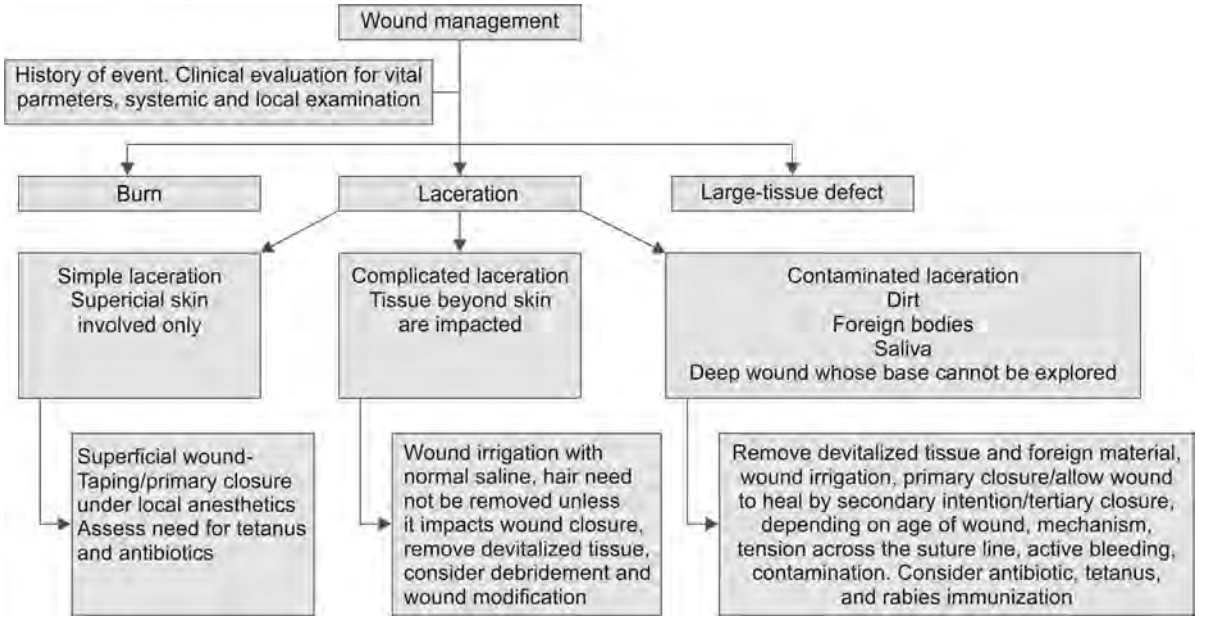
TABLE 8: Postclosure wound care and follow-up.

Type of wound	*Dressing*	*Follow-up*
Simple laceration/ abrasion	Topical antibiotics/ sunscreen/Vaseline/ clothing if exposed to sun	Not required
Complex laceration and wound healing by secondary intentions or delayed primary closure	Topical antibiotics and simple nonadherent dressing	5 days
Complex hematoma/ contusion	Gentle compression and elastic wrap	1 week
Puncture and bite wound	Topical antibiotics and nonadherent dressing	5 days
Abscess	Loose packing/ nonadherent dressing	24–48 hours

Sutures over joints or areas with a lot of movement should stay in for 10–14 days. Also, lacerations overlying joint surfaces should be splinted in the position of function for up to 10 days (**Table 8**).

SUMMARY

To treat wounds properly, the emergency physician needs knowledge of basic wound physiology along with host and wound factors affecting healing. Although many types of wound closure techniques are available, the choice of closure needs to be appropriate for the wound (**Flowchart 1**). Wound and host factors affect the type of closure that is best for different types of wounds. Bite wound is managed as per **Flowchart 2**. To obtain the ideal functional and cosmetic result without complications should be the ultimate goal.



Wound management
History of event. Clinical evaluation for vital parmeters, systemic and local examination
Burn
Laceration
Large-tissue defect
Simple laceration Supericial skin involved only
Complicated laceration Tissue beyond skin are impacted
Contaminated laceration Dirt Foreign bodies Saliva Deep wound whose base cannot be explored
Superficial wound-Taping/primary closure under local anesthetics Assess need for tetanus and antibiotics
Wound irrigation with normal saline, hair need not be removed unless it impacts wound closure, remove devitalized tissue, consider debridement and wound modification
Remove devitalized tissue and foreign material, wound irrigation, primary closure/allow wound to heal by secondary intention/tertiary closure, depending on age of wound, mechanism, tension across the suture line, active bleeding, contamination. Consider antibiotic, tetanus, and rabies immunization

237 CHAPTER

Advanced Laceration Management

Aditya Agarwal, Sukhdeep Singh

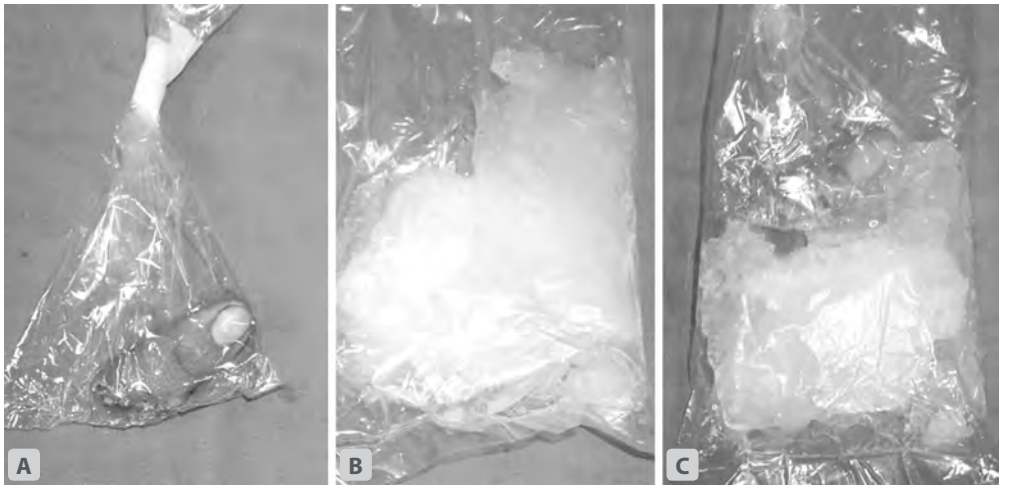
INTRODUCTION

Many lacerations which are specifically based on anatomic location require specific management in the emergency department. Advanced management techniques are required to manage for the repair of complex lacerations of the fingertip, ear, nose, lip, tongue, and eyelid. Since these lacerations are complex and aesthetically important, to avoid any further litigations it is important for the emergency clinician to know when specialist consultation is appropriate for treatment. In addition to routine triage of lacerations described in the previous chapter, some special considerations are needed while handling lacerations including ones that are periorbital, ear, nose, lips, tongue, and scalp. This chapter includes initial management, methods of repair, technical tips to facilitate repair, appropriate consultation, and postoperative care for these complex lacerations.

INITIAL MANAGEMENT

Initial treatment includes resuscitation of both airways and circulation. Any active vascular hemorrhage can initially be controlled by direct digital pressure; clamps may then be applied if the vessel can be clearly visualized. Blind clamping of a bleeding vessel is not recommended due to the risk of damaging adjacent tissue, especially nerves. Tourniquets are best avoided in routine due to the risk of compression injury to nerves, occlusion of veins resulting in the compartment syndrome, and increased chances of venous thrombosis yet maybe lifesaving in some cases. After identification of the vascular injury, a management strategy should be developed consistent with the clinical condition of the patient, severity of the injuries, and resource availability. In case the patient has to be moved to another center, cooling the ischemic limb will minimize warm ischemia time. For this to be accomplished, the limb is wrapped in towels, and ice in plastic bags is applied around the limb, avoiding direct contact of the ice to the limb, which can result in cold ischemic injury (frostbite) (**Figs. 1A** to **C**).

Wound care: Injured patients present with a myriad of different wounds depending upon the injury mechanism. Upon admission, the location and size of each wound should be documented. Deep and more extensive wounds, particularly



FIGS. 1A TO C: Dry cooling for transfer of the amputated part. (A) Finger in a clean plastic bag; (B) Ice in a separate plastic bag; (C) Bag with a finger placed such that the finger does not have direct contact with the ice. ***(For color version, see plate 45)***

those in proximity to major vessels, should be explored in the operating room where lighting is optimal, debridement can be undertaken, and any disrupted vessels can be managed in a controlled fashion. Individual wounds are managed with moist dressings and closure or coverage, as indicated.

DIAGNOSTIC WORKUP

Investigations needed will include complete blood count, renal function tests, coagulation parameters, and serum lactate level (as a marker of end-organ perfusion) that can serve as a guide for ongoing resuscitation.

Other investigations that may be needed include the following:

- *Plain radiography*: Plain radiographs of the affected extremity to detect fractures, joint penetration, and foreign bodies
- *Hand-held Doppler and ultrasound*: In case pulses are not palpable in an injured extremity
- *Ankle-brachial index and arterial pressure index*: In an effort to improve on the accuracy of physical examination without relying on expensive and invasive tests such as arteriography, the use of blood pressure in the injured versus the uninjured extremity [arterial pressure index (API)] or the blood pressure in an injured leg at the ankle compared with brachial artery pressure [ankle-brachial index (ABI)] was developed and validated in numerous studies as an accurate means of detecting vascular injury.
- *Computed tomography and magnetic resonance imaging*: *Computed tomography* (CT) with contrast enhancement [computed tomography angiography (CTA)] has become the standard of care for the detection of peripheral vascular injury in most trauma centers. Magnetic resonance imaging (MRI) is contraindicated in the presence of iron-containing metallic foreign bodies.
- *Arteriography*: Arteriography and digital subtraction angiography (DSA) may be used for assessing vessels before any surgical exploration.

SELECTION OF SUTURES AND SUTURING METHODS

Sutures may be monofilamentous (prolene or ethilon) or multifilamentous (silk). The designation for suture strength is the number of zeros; the higher the number of zeros (1-0 to 10-0), the smaller the size and the lower the strength (**Table 1**). They can also be defined as absorbable (dissolve within 14–180 days) or nonabsorbable. Pediatric injuries are managed similarly but may require general anesthesia.

PERIORBITAL WOUND

Eyelid lacerations should be carefully evaluated for the involvement of the lid margin and any tissue loss. They tend to follow relaxed skin tension lines. Management includes:

- Careful evaluation excluding any for any injury to the globe
- Protection of the cornea
- Excluding the presence of any foreign body
- Minimizing the risk of infection
- Optimizing cosmesis

History of the Injury

In addition to standard information, carefully ascertain the presence of any foreign body and tissue loss. Animal or human bite wounds may result in infection and should be appropriately managed for rabies, human immunodeficiency virus (HIV), and hepatitis. In cases of small penetrating lid lacerations, maintain a high index of suspicion for underlying globe trauma. Document carefully the prior visual acuity. Patients who are inebriated or children may not be good historians and one should be essentially careful while evaluating them.

Examination of the Eye

Look for any gross injury. Evert the lids only in the absence of globe rupture and flush the fornices. Palpate and examine the lids for foreign bodies, including contact lenses. Examine the

TABLE 1: Sutures and suturing methods for advanced laceration.

Laceration parameters	*Type of needle*	*Type of suture*	*Special suturing techniques*
Superficial facial lacerations	Reverse cutting	Prolene or ethilon (6-0)	Simple interrupted skin sutures
Deep facial lacerations (layered closure)	• Reverse cutting • Reverse cutting	• 5-0 PDS or Monocryl • Prolene or ethilon (6-0)	• Subdermal interrupted sutures • Simple interrupted skin suture
Tongue	Taper cut	4-0 or 5-0 Vicryl	Vertical mattress sutures
Oral mucosa	Taper cut	4-0 or 5-0 Vicryl	Vertical mattress sutures
Eyelid	Taper cut	6-0 silk or prolene	Simple interrupted skin sutures
Nailbed	Reverse cutting/taper cut	6-0 or 7-0 plain catgut	Simple interrupted sutures
Limbs and torso	Reverse cutting	4-0 or 5-0 ethilon or prolene	Simple interrupted sutures or vertical mattress sutures
Suture removal: The timing of suture removal varies with the anatomic site. • *Eyelids*: 2–3 days • *Neck*: 3–4 days • *Face*: 5 days • *Scalp*: 7–14 days • *Trunk and upper extremities*: 8–10 days • Lower extremities: 8–10 days			

(PDS: polydioxanone)

cornea for any lacerations, tears, or foreign bodies. Carefully observe all ocular movements including intrinsic and extrinsic muscles of the eye. Damage to the tarsal plate, ptosis, injuries to the lacrimal duct system, canthi, or lid margins should be referred to an oculoplastic surgeon for repair.

Preclosure Workup

Investigations in addition to the routine ones must include HIV, hepatitis serology, and when needed a CT scan to exclude foreign bodies, retrobulbar hemorrhage, globe rupture, or an orbital fracture. Antibiotics and tetanus prophylaxis may be given as previously discussed.

Anesthesia and Pain Relief

Most adults can be operated for lid repair under local anesthesia (topical anesthetic drops and topical lidocaine gel, anesthetic with epinephrine) in the emergency itself, yet uncooperative patients or children may require general anesthesia. A loupe magnification is useful in wound exploration and repair.

Surgical Management

Assessment and management of eyebrow lacerations are shown in **Figures 2A** and **B**. A careful inspection of the orbital rim and palpation of the circumference can help to identify underlying fractures and displacement of the rim. The eyebrow should never be shaved because the hairline cannot be visualized and that is critical for the correct alignment and additionally regrowth of the hair is unpredictable (**Figs. 3A** and **B**).

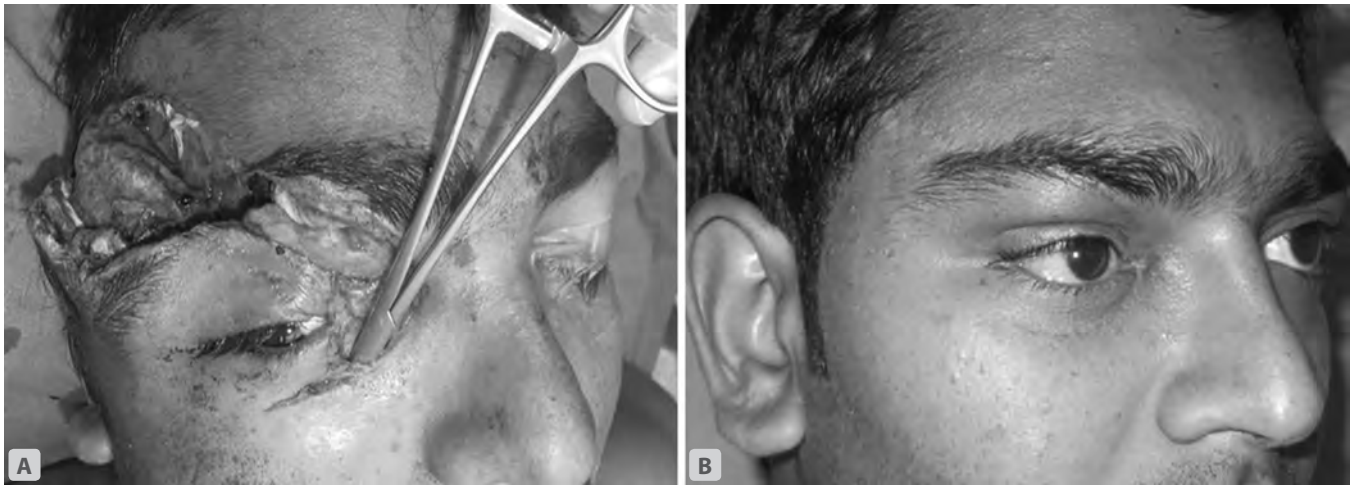
Combined Injuries

If a patient has a ruptured globe and a lid laceration, the globe rupture must be repaired first (**Figs. 4A** and **B**). If the lid repair must be delayed in favor of more life-threatening injuries, ensure adequate corneal lubrication and consider systemic antibiotic coverage. It is beneficial to try and save all lid tissue as the ocular adnexa has a good blood supply, and even ischemic-appearing tissue will often heal.

FIGS. 2A AND B: (A) Clean lacerated wound of the right eyebrow (no need to shave the hair); (B) Good eyebrow alignment after 1 week. ***(For color version, see plate 45)***

FIGS. 3A AND B: (A) Clean lacerated wound of the forehead and eyebrow; (B) A single stitch taken to align the eyebrow prior to a primary repair of the remaining wound. ***(For color version, see plate 45)***

FIGS. 4A AND B: (A) Complex periorbital laceration involving the eyebrow, lid, and lateral canthus; (B) Results after 6 months—careful anatomical alignment maintained during the repair. ***(For color version, see plate 46)***



FIGS. 5A AND B: (A) Complex periorbital injury showing disruption of the medial canthus with nasolacrimal duct injury and facial skin avulsion following a road traffic accident; (B) Late postoperative (6 months) results of a primary repair and fixation of underlying fractures. ***(For color version, see plate 46)***

NASOLACRIMAL DUCT INJURIES

Suspect these in cases of lacerations near the medial canthus of the eye. Once identified, these need to be repaired under magnification, which is best done by an oculoplastic surgeon (**Figs. 5A** and **B**).

CHEEK LACERATIONS (ZYGOMA)

Deep lacerations to the cheek, just anterior to the ear, have the potential to injure the parotid gland or the facial nerve. If the parotid gland is injured, bloody fluid can be seen leaking from the parotid duct via the buccal mucosa at the level of the maxillary second molar (**Fig. 6**).

EAR LACERATIONS

Wound closure on the ear can proceed in a standard fashion when the cartilage is not involved. The cartilage should not

FIG. 6: Poorly stitched oblique cheek laceration with parotid duct injury. The wound was re-explored and the parotid duct repaired. ***(For color version, see plate 46)***

be sutured if at all possible, because of the risk of infection. If suturing is necessary, the perichondrium must be included in the stitch in order for it to hold. The goal in repairing a wound with exposed cartilage is to cover it with skin as completely as possible. Blunt trauma may cause perforation of the tympanic membrane and a high degree of suspicion must be kept to exclude the same (**Figs. 7A** and **B**).

NOSE LACERATIONS

An injury to the nose is fairly obvious due to deformity of the nose or epistaxis. Performing an adequate and thorough nasal examination is difficult without epistaxis control. The origin of most nosebleeds is the vascular area on the anterior septum. Once the bleeding is controlled, by pinching the same or nasal packing, an intranasal inspection using a nasal speculum should be performed. The nasal septum (for hematomas), turbinates, and inferior meatus should be visualized bilaterally. Mucosal lacerations may be the sign of underlying fracture and should be carefully noted. Cerebrospinal fluid (CSF) rhinorrhea should be suspected in case of significant trauma. Septal hematoma if not identified in time can result in a continuous pressure on the septal cartilage resulting in necrosis and deformity (**Figs. 8A** to **C**). Septal hematoma is best managed by decompression (by a large gauge needle or by incision and drainage) followed by bilateral nasal packing.

SCALP LACERATION

As it is a highly vascular structure, the bleeding may be disproportionate to the size of the injury. After cleaning the wound, hemostasis with direct pressure application must be done to stop the bleeding before further evaluation should be attempted with direct pressure (**Figs. 9** and **10**).

LIP LACERATION

It is especially critical that lip lacerations are repaired correctly to preserve the cosmetic appearance and functionality of the lip. Disruption of the vermilion border should be noted as a failure to do so can lead to do a significant cosmetic deformity. A step-off of the vermilion border as small as 1 mm is apparent at a close distance. Inspect inside the mouth and lips in case of every facial injury for any through-and-through wound, carefully evaluating the parotid duct area and inspecting for any disrupted teeth and hematomas (**Figs. 11A** and **B**).

Complex Lip Laceration

Unlike the cosmetically important facial lacerations that are almost always closed primarily, certain small intraoral lacerations may be left open and will heal well without repair. Intraoral closure is needed when the mucosal laceration

creates a flap or is large enough to trap food particles or is longer than 2 cm (**Figs. 12A** and **B**).

Vermilion border: If the vermilion border is involved, approximate it with the first suture placed on facial skin. Use 6-0 ethilon/prolene suture. In young children, consider using absorbable sutures for the repair of these lacerations.

Intraoral skin: It may be closed either before or after the facial skin. Approximate the buccal wet mucosa with simple interrupted absorbable sutures (4-0 or 5-0); absorbable sutures fall out or absorb and do not require removal. However, do not use fast-absorbing sutures on mucosal surfaces. Secure each stitch with four or more knots to ensure that the stitches are not untied by the tongue. These sutures can be continued onto the wet and dry vermilion surface of the lip. Silk is best avoided in the mouth, as it can irritate mucosal tissues. Any small intraoral flaps may be excised. If a patient with a lip or oral laceration also has a newly chipped tooth, search diligently for tooth fragments in the oral mucosa because if these are not removed, they may cause wound infections. *Facial skin*: Using 6-0 sutures, approximate the skin with simple interrupted sutures. This suture material can be continued onto the lip. Many prefer absorbable sutures on the dry vermilion surface.

TONGUE LACERATION

All tongue lacerations will not need a repair but must be carefully evaluated for depth of the injury and any foreign bodies. An exception is the complete anterior laceration, which should be repaired properly else it can result in a bifid tongue (**Figs. 13A** and **B**).

FACE LACERATION

In the case of any traumatic accidental injury, the face should be inspected and palpated for any asymmetry. The facial expressions and the related nerves should be evaluated by raising eyebrows, closing eyes, smiling, and frowning (**Figs. 14A** to **D**).

Repair: Superficial wounds may be repaired in a single layer, but deeper wounds should be repaired in layers. If muscle

FIGS. 12A AND B: (A) Complex lip laceration following a road traffic accident showing a through-and-through avulsion of the lower lip with other facial injuries. A three-layer repair (mucosa, muscle, and skin); (B) Results on postoperative day 30. ***(For color version, see plate 48)***

FIGS. 13A AND B: (A) Deep through-and-through laceration of the tongue that was repaired by a layered closure with a 5-0 Vicryl; (B) Intraoperative results. ***(For color version, see plate 49)***

FIGS. 14A TO D: (A) Patient reported with a facial nerve palsy following facial laceration repair at a primary care unit; (B) Operative picture showing the exploration of the wound and identification of the facial nerve injury; (C) Gradual recovery of the repaired facial; (D) Complete recovery. ***(For color version, see plate 49)***

layers are not repaired, they may result in puckering and scarring. When performing a two-layer closure, the deeper layers should be closed with absorbable sutures and the skin with a nonabsorbable monofilament suture. *Dermal adhesives* have shown equivalent efficacy for simple clean wounds as sutures. The advantages of dermal adhesive use include a shorter repair time, less pain, and no need of follow-up stitch removal. The disadvantages are that they cannot be used on the lips or mucous membranes. *Staples* may be conveniently used in scalp lesions, need a shorter repair time, and have similar rates of infection. Disadvantages include the lack of precision in alignment of the wound edges, thus limiting the use to of the scalp.

HUMAN BITES

Human bites have a preponderance to become infected due to the bacterial inoculum in the saliva and the fact that most injuries involve the hands and hand wounds have a higher rate of infection regardless of etiology. Recognition of the risk of infectious complications and early aggressive treatment are the thumb rules to prevent serious wound infection.

Human bite wounds occur as two separate entities: (1) *Clenched-fist injuries and* (2) *occlusive bites.*

Clenched-fist injury: These occur when a closed fist strikes the teeth of another individual with force enough to create an injury. The injury usually occurs over the dorsal surface of the third and fourth metacarpophalangeal (MCP) or proximal interphalangeal joints of the dominant hand. As the skin in these areas is thin, there may be penetration of joints and injuries to extensor tendons.

Occlusive bites: These occur when there is sufficient bite force to break the skin. Such injuries to the hand/finger when a finger is bitten must be carefully evaluated to rule out deeper tendon injuries. Bites to the head and neck can result in avulsion, laceration, and crushing of the tissues. Such injuries in small children must be reviewed carefully for depth of injury beyond the obvious in addition to legal considerations of suspected abuse.

Wound characteristics: Assess all bites for location, shape size, depth, associated laceration, avulsion, crush, or any retained foreign or particulate matter Additionally, note for any neurovascular or tendon injury.

FIG. 15: Soft-tissue deficit of the upper lip following a human bite, which will require an expert plastic surgical repair. ***(For color version, see plate 49)***

Puncture wounds: These are the most common around the head and are difficult to clean due to the depth of the wound. Explore the depth by extension of the neck, irrigation, and investigations such as X-ray or CT scans to identify the presence of any debris. They are best left open and secondarily closed. As they are prone to infections, appropriate antibiotics are a necessity.

Ear bites: Ear wounds are also common due to their prominent location. Small bites may be closed primarily and bigger ones may need a wedge excision. It is important to cover any exposed cartilage and restore its original shape.

Nose bites: Nose wounds and resultant nose reconstruction can be challenging and may need plastic surgeon's opinion for the same. Bites to the ear or nose or lips—are best closed in consultation with a plastic surgeon (**Figs. 15** and **16**).

Wound closure: In general, we do not primarily close deep puncture wounds, hand wounds, or wounds older than 12 hours. They may be closed secondarily or revised at a later date. Clean and uncontaminated head and neck wounds less than 12 hours of age may be closed primarily and heal well due to excellent blood supply. Antibiotic prophylaxis is mandatory in patients with bite wounds. Ensure closure in a simple interrupted fashion with good edge approximation and

yet allowing drainage. Tetanus prevention is recommended as previously discussed.

SPECIAL CONSIDERATIONS FOR ANIMAL BITES (DOG AND CAT)

As with human bites, primary closure is suggested only in facial wounds younger than 8 hours. Puncture wounds or contaminated wounds or those older than 12 hours may be better left open for healing with a delayed closure (**Figs. 17A** to **C**). Treatment with prophylactic antibiotics for 3–7 days is recommended. Tetanus immunization is recommended as previously discussed

Rabies immunization: If the laceration is due to the bite of a wild animal, complete rabies prophylaxis must be given. If a domestic pet was the culprit, check the pet's rabies immunization status and quarantine the animal for 10 days. In case it is not possible to quarantine the animal, the bite victim should receive the rabies immunization. Rabies immunization should begin within 48 hours after the bite and consist of active immune cover with a vaccine and passive immune cover with rabies immunoglobulin.

FIG. 16: Human bite on the nose with subtotal nasal loss which will require a complex plastic surgical repair. ***(For color version, see plate 49)***

LIMB INJURIES

Injuries to limbs may be simple or complex with neurovascular or deeper tissue They may be caused due to blunt or penetrating trauma or a combination of blunt and penetrating trauma (such as bull goring injuries) (**Figs. 18A** and **B**).

Evaluation of Limb Injury

History: Note carefully the time of injury (to evaluate the warm ischemia time) and the types of injury: Crush or bites are more prone to infections and any coexistent medical conditions (such as diabetes, immunocompromise, and vascular insufficiency that can impair wound healing). Open avulsion injuries of limbs are severe because the skin is the last structure to tear much later than vessels and nerves. The vascular injury also should be suspected in patients with massive soft-tissue avulsion or crush injury, displaced long-bone fractures, electrical or lightning injuries, and severe burns as well as in those with compartment syndrome from trauma or prolonged immobilization as a result of stroke, coma, drug overdose, or other causes. Large animal bites are particularly prone to arterial injury and wound complications.

Physical examination: Careful physical examination including palpation of the peripheral pulses and recording blood pressures in both affected and unaffected limbs is important in the diagnosis of nonobvious vascular injury (**Table 2**). *The classic findings of vascular injury* include pulsatile bleeding, loss of distal pulses, audible bruit, or palpable thrill. Findings such as pallor, cyanosis and cold extremities, and distension of superficial veins may indicate an arteriovenous (A-V) fistula. Wounds that are close in proximity to neurovascular bundles must be carefully evaluated to rule out vascular injuries. Detection and management of vascular injuries are done in accordance with established principles of trauma care with the resuscitation of the patient. Once the source of bleeding is identified, it is compressed with digital pressure.

CRUSH INJURIES

In recent years, physicians have seen an increase in the number of crush injuries. Larger population densities coupled with impoverished conditions result in large groups of people living in close proximity in buildings with poor structural integrity.

FIGS. 17A TO C: (A) Pet dog bite with a through-and-through disruption of the upper and lower lips (front view); (B) Pet dog bite with a through-and-through disruption of the upper and lower lips (lateral view); (C) Results at postoperative day 30. ***(For color version, see plate 50)***

Modern warfare and large-scale natural disasters, such as earthquakes or tsunamis, can be an inciting event. Collapsing structures result in a large number of people being trapped by rubble, and thus we have seen an increase in the number of crush injuries from these events. Crush injury-related renal failure and wound infection are complications that can be treated with the appropriate resources and training.

Pathophysiology: Crush syndrome was first described in the literature by Bywaters and Beall in 1941. Their observations came from taking care of soldiers who were crushed during bombing raids in London during the Blitz. It was recognized during this time period that myoglobin deposition in the kidneys was responsible for renal failure. Since that time, numerous observations have been made regarding crush syndrome demonstrating the involvement of many organ systems.

Complications secondary to crush syndrome: Limb injury, amputation, acute renal failure, acute respiratory distress, disseminated intravascular coagulation, bleeding and hypovolemic shock, cardiac failure, arrhythmias, electrolyte disturbances, psychologic trauma

Following the initial insult to muscles various processes occurs during crush syndrome. After a muscle cell is crushed or stretched, potassium and myoglobin are released from the damaged cell. Also, damaged cells absorb water, calcium, and sodium from the extracellular space through leaky sarcolemma. A large efflux of potassium from these cells can result in hyperkalemia and the secondary cardiotoxicity that results from it. The myoglobin is released from the cells along with urate and phosphate, which precipitates in the distal convoluted tubules and forms casts leading to obstruction. Metabolic acidosis and hypovolemia potentiate this problem in the renal tubules. Acidemia causes myoglobin to form a gel, which leads to decreased urine output and acute renal failure. Oligemia, hyperkalemia, hypocalcemia, and uremia progress to death in 3–7 days, if untreated. In addition to the renal disaster, there are other medical issues in patients involved in significant crush injuries. There is the risk for infection and subsequent sepsis from the initial crush injury and also from fasciotomy sites. Patients are also susceptible to acute respiratory distress syndrome following such a systemic insult. Additionally, if crush injuries result in bony abnormalities, fat embolism syndrome must be considered in the differential diagnosis.

Prehospital care: This is of great importance in patients involved in significant crush injuries. The rate of complications, such as renal failure and compartment syndrome, is inversely proportional to the elapsed time from injury to prehospital medical care. Primary management of airway, breathing, and circulatory issues must be addressed before transport. Normal saline should be administered to these patients because of the risk for worsening pre-existing hyperkalemia and the inability to accurately monitor urine output in these patients. The eventual goal is to maintain urine output at 1–2 mL/kg/h. Hemorrhage must be controlled, and some would argue for the early administration of antibiotics in these patients.

Hospital management: These patients arrive with multiple issues that need to be addressed. Specifically, primary trauma can result in issues regarding hemorrhage, pneumothoraces, and unstable fractures that need to be managed concurrently. Some patients require fasciotomies, whereas some have already received such therapy in the prehospital environment.

Fluids: Fluids are a key component to resuscitation in an effort to maintain peripheral organ perfusion and specifically preserve renal function. Initially, normal saline can be used, but eventually, potassium- and glucose-containing solutions are needed. Many suggest alternating between normal saline and a glucose solution in an effort to keep as many electrolytes in balance as possible. Large amounts of fluid can be required, sometimes upward of 12 L in the first 48 hours. A reasonable goal is to maintain urine output at 200–300 mL/h.

Alkalinization: Alkalinizing the urine of patients undergoing rhabdomyolysis secondary to crush syndrome has been a proven technique for some time. Urinary alkalinization increases the solubility of myoglobin and minimizes the formation of gel that causes tubule obstruction and subsequent oliguria. There are numerous suggested regimens in the literature to achieve urinary alkalinization. One such model is to add 50 mmol bicarbonate to the initial fluid boluses with a goal of keeping urine pH greater than 6.5.

Mannitol: Although somewhat controversial, many authors suggest that the use of the osmotic diuretic mannitol as an adjunctive therapy in crush injury patients improves outcomes. The suggested dose is 1–2 g/kg of 20% solution administered over a 4-hour period. It is believed that this creates a forced diuresis, thereby increasing urine output and helping to wash out tubular myoglobin. Mannitol also has the potential benefit of reducing intracompartmental pressures (which could potentially decrease the need for fasciotomies) and protecting the kidneys from oxidative injury by acting as a free radical scavenger. As an intravascular volume expander, it must be monitored closely and should not be given until urine output is established in the patient. Electrolytes, osmolarity, and urine output must be monitored closely while administering mannitol.

Renal failure: Despite physicians' best efforts, some patients succumb to acute kidney injury. Patients who have complete failure of their kidneys need dialysis. Patients with crush syndrome who require dialysis should continue this therapy for 13–18 days.

Compartment syndrome: This results when injured muscle cells increase in size with intracellular fluid uptake while total space remains constant. This swelling results in increases in intracompartmental pressures. As pressure increases, blood flow to the damaged tissue decreases resulting in tissue ischemia and eventual necrosis. It is classically taught that increased pressures resulting in tissue ischemia for >6–8 hours result in permanent damage. The treatment for compartment syndrome is fasciotomy. This procedure allows the swelling muscle to expand outside of its compartment, thereby preserving afferent blood flow. Fasciotomy continues to be a controversial subject in the realm of crush syndrome management. Some authors argue that this is a lifesaving intervention that also decreases the risk for complications related to crush syndrome. Other studies have not shown such profound benefits with fasciotomy. The benefits of fasciotomy must be compared with the outcomes related to localized wound infection, sepsis, subsequent amputations, and increased mortality.

Additional treatment modalities: In general, surgical amputation is not a recommended course of action in patients who have crush syndrome and should be considered a last resort in all patients. Even consensus statements recommend this only as a last resort because many severely crushed limbs can return to near or full function. There is some evidence that exposing crush injuries to subatmospheric pressures lowers serum myoglobin levels. Further research involving human subjects is needed to quantify when this therapy should be initiated in patients. Additionally, hyperbaric oxygen (HBO) could be an effective adjunctive therapy for crush injury patients.

Infections and wound management: These are concerns for the provider when patients make it out of the acute phase in which renal failure predominates. These patients who have crushed extremities have varying severity of wounds, but the one common feature is that they are all dirty wounds. Both endogenous and exogenous bacteria are introduced into an open wound site following these types of injuries. This, combined with the loss of the protective skin barrier, makes these patients susceptible to infection, sepsis, and risk for death. Also, the main site of infection risk is the fasciotomy site following a few days of hospitalization. The use of fasciotomies, especially in the prehospital environment, remains controversial and this study demonstrates the increased infection and mortality complicated by this surgical procedure.

SUMMARY

Advanced and difficult wounds constitute a significant amount of the morbidity and mortality emergency physicians face on a daily basis. There are specific traumatic and atraumatic wounds that are difficult to manage and have a high risk of complications. Emergency physicians must be able to identify these high-risk wounds and patients and take steps to mitigate further morbidity and mortality.

CHAPTER

Burns

Gaurav B Shetty, Sahanya Ramesh Shetty

INTRODUCTION

According to the World Health Organization, about 3,22,000 die after fire-related burns every year throughout the world. This is still an underestimate of the actual deaths caused by burns in developing countries which accounts for more than 95% of these deaths. Factors attributing to increased incidence of burns in developing countries are illiteracy, high population intensity, poverty, and unsafe cooking methods. The management and treatment of burns are not always easy. However, the points to be taken into consideration are that the initial 24 hours are critical and are linked to morbidity and mortality. In order to initiate adequate and optimal care to burn victims, health care personnel need to understand the pathophysiology of burn injuries, their classification, and the appropriate use of surgical treatment. This knowledge is deemed to be important as there is a small window of opportunity to revive a burnt patient. Depending upon the severity of the condition, some patients may be treated in the hospital emergency department, while others may require transfer to a tertiary burn care center after initial stabilization and resuscitation.

What factors influence outcome?

A study of survival data from patients of burn-related injuries from the Massachusetts General Hospital revealed three factors that cause death: (1) Age above 60 years, (2) burn surface area above 40%, and (3) smoke inhalational injury (SII).[2] As the outcome of survival has improved with decreased mortality to about 5–6% in resourced centers, the assessment of outcome has shifted from mortality to quality of life. Hence, the main agenda for burn patients involves preservation of function, reconstruction, and rehabilitation. The pathophysiological process which is responsible for outcome is shown in **Flowchart 1**.

ETIOLOGY

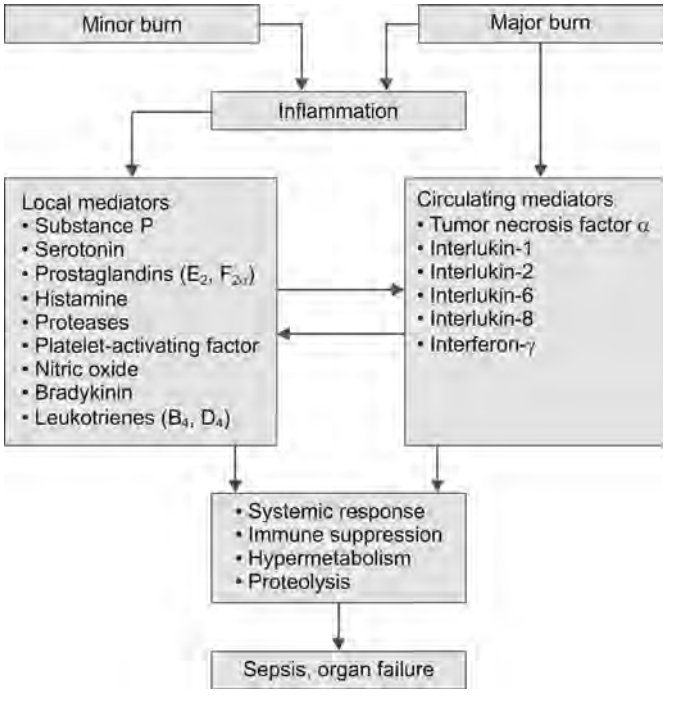
- Flame burns (thermal burns)
- Scalds (hot liquids)
- Steam
- Contact burns (hot objects and articles)
- Chemicals (acids or alkalis)
- Electrical burns (high and low voltage)
- Sunburns
- Friction burns
- Radiation burns
- Burns from a lightning strike

DETERMINING THE SEVERITY OF BURN: CLASSIFICATION

Determining burn severity depends on the involvement of the total body surface area (TBSA) and depth of the burn.

Severity on the basis of TBSA involvement: *TBSA*: The estimation of adult burns by *Wallace's "rule of nines"* (**Fig. 1A**):

- 18% each for back, chest, and legs (individually)
- 9% for each arm and head, 1% for perineum
- Though being an efficient tool to evaluate the percentage of burn over body surface, it overestimates the area by 3%.



FLOWCHART 1: Pathophysiology of burn.

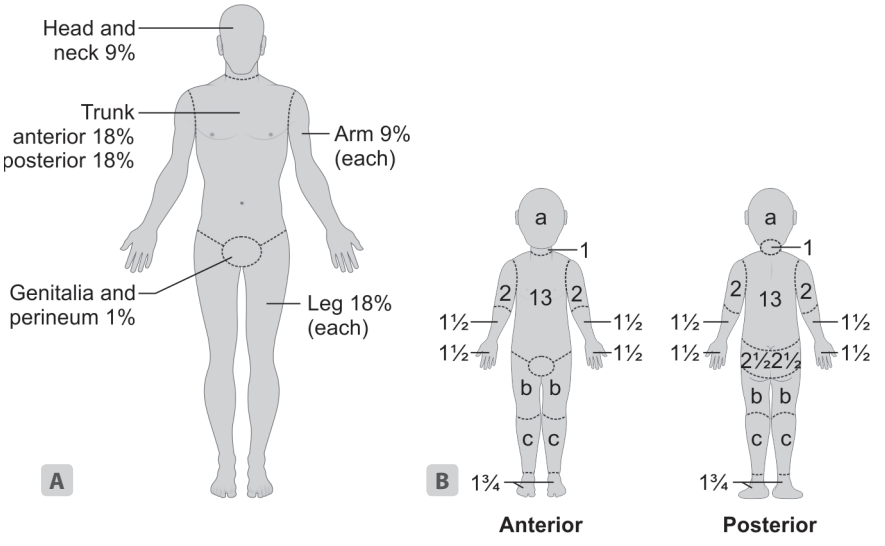
Lund and Browder's chart: It takes into account changes in body surface area with age and growth. It is helpful in the estimation of burns in all age groups (**Fig. 1B**). Another modality to estimate surface area is by the area on the volar aspect of hand inclusive of fingers. This is essential in determining small burns (<15%) or large burns (>85%). In larger areas of burn, the total area affected can be calculated by estimating the areas not burnt and then subtracting it from 100. One of the pitfalls is the addition of the erythema, which will present an overestimate of the calculation.

Severity on the Basis of Depth of the Burn

Clinical estimation of burn depth is often subjective. An independent blinded comparison among experienced surgeons showed only 60–80% concurrence. Burn wounds are dynamic and need reassessment in the first 24–72 hours because depth can increase after the injury as a result of inadequate treatment or superadded infection. Burn wounds can be superficial in some parts but deeper in other areas (**Figs. 2A** and **B**).

First degree: These consist of an intact epidermis in the presence of erythema, e.g., sunburn.

Second degree: The integrity of the epidermis is intact. When the extent of burn is limited to the upper layers of dermis, it is a superficial second degree. Burns progressing toward deeper reticular layers are termed a deep second-degree burn. In contrast, superficial burns are more painful, while deeper second-degree burns have decreased pain and a blunt pressure feeling in affected areas.



Relative percentage of body surface area (% BSA) affected by growth

	Age				
Body part	**0 years**	**1 years**	**5 years**	**10 years**	**15 years**
a = 1/2 of head	9 1/2	8 1/2	6 1/2	5 1/2	4 1/2
b = 1/2 of 1 thigh	2 3/4	3 1/4	4	4 1/4	4 1/2
c = 1/2 of 1 lower leg	2 1/2	2 1/2	2 3/4	3	3 1/4

FIGS. 1A AND B: (A) Rule of nine for adult; (B) Lund–Browder chart for children for estimating the extent of the burn.

FIGS. 2A AND B: (A) Partial thickness with partial thickness superficial burn noted on abdomen and bilateral thighs having partial-thickness superficial burns; (B) Flame burns: Upper extremity circumferential burns, causing a tourniquet effect on the distal forearm and hence predisposing to compartment syndrome. ***(For color version, see plate 50)***

Third degree: These involve all layers of the dermis. The skin may present as dark, dry, hard and painless. Thrombosis is present inside the blood vessels along with a typical eschar formation.

Fourth degree: These include all layers of skin with subcutaneous fat and deeper tissues. There is a carbonized appearance with muscles and tendons involved.

Superficial burns: The extent of injury involves minimal or no dermal injury. They consist of superficial second-degree burns and first-degree burns. They usually heal within 3 weeks without any sequelae.

Deep burns: The injury involves the dermis completely or partially. They consist of deep second-, third-, and/or fourth-degree burns, depending on the extent of the dermal injury and underlying deep tissues. The healing process involves a period of >3 weeks and may require surgical intervention.

Some characteristic features of burns of varying depths are summarized in **Table 1**. The terms "partial-thickness" or "full-thickness" burns describe the level of burn injury and indicate the likelihood and estimated duration for healing to occur.

INITIAL MANAGEMENT OF BURN

Burn Care in a Prehospital Setting

- Circulation, airway, and breathing are examined at first. In a patient sustaining multiple trauma injuries, one must apply the "forget the burn" principle; resuscitation of life-threatening injuries is a priority.
- The victim should be rescued from the site and extinguished of the fire.
- For minimal burns, it should be kept under running tap water for the initial 20 minutes, in order to alleviate the ensuing thermal damage and cease the process of further thermal damage.
- In cases of hot liquid burns, all wet clothes need to be removed.
- *Flame burns*: The idea is to move the patient away from the source. If not possible, fire is extinguished. Assessment for carbon monoxide and smoke inhalation is essential. Early administration of 100% oxygen is beneficial. If required in extreme cases, endotracheal intubation is done.
- In electrical burns, there are three types of injuries possible: (1) Electrocution, (2) Flash burns, and (3) arc Burns. One must ensure that electricity is turned off and the patient is moved away from the source of electric current. Assessment for need of cardiopulmonary resuscitation is evaluated. Check for multiple traumas, including blunt or penetrating injuries.
- In chemical burns, all dry chemicals need to be brushed off and rinsed under running water angulated at a tangent to the skin until the pain is relieved (this could take 60 min). However, care must be taken to prevent hypothermia. In most cases, neutralizing agents are contraindicated due to exothermic reactions. Avoid immersing the patient in a tub of water.

TABLE 1: Classification of burns on the basis of extent and depth.

		Second degree			
		Partial thickness			
Degree of burns	***First degree***	***Superficial***	***Deep***	***Third degree***	***Fourth degree***
Depth of burn	Epidermal	Superficial dermal	Deep dermal	Full thickness	Deep organ involvement
Sensation	Painful	Painful	Painful (varied sensation)	Insensate	Insensate
Clinical features	Blisters – Blanches +	Blisters+ (blanching + on unroofing the blister)	Blisters ± Blanching –	Blisters – Blanching –	Blisters – Blanching –
	Erythematous, red, glistening	Erythematous, pink + (on unroofing the blister)	Pale +, molting +, white +	Leathery Dry –, brown/black white +, leathery +, eschar +	Involves bone/ fat/ muscles
	Moisture + Exudates +	Moisture + Exudates +	Moisture + Exudates +	Moisture – Exudates –	Moisture Exudates
Examples	Sunburn	Scald injury	Hot grease injury	House fire, sustained burn	Electrical burn and extensively sustained burn
Healing	Scar less healing within 7–14 days	2–4 weeks	• 3–8 weeks • Severe scarring +, needs grafting	Needs grafting	4–11 weeks
Intervention		• Heals without grafting • Collagen application	Tangential excision + split-thickness skin grafting	Tangential excision + split-thickness skin grafting	Needs grafting/soft-tissue cover

- Establish a large intravenous access for major burns, and the choice of fluid should be Ringer's lactate solution for resuscitation. Observation of circulation, urinary output, and respiration is essential. The complete picture of the event and medical conditions of the patient should be obtained. In cases of transfer to other burn centers, one must provide detailed information of the severity of burn and the medical condition of the patient prior to transfer.
- One must anticipate edema formation in larger burns. Hence, removal of jewelry including rings, chains, necklaces, and bracelets is done. This is done for two reasons as these metals are heated and then dissipate a latent heat and the other reason being the edema that ensues making it difficult later on to remove these constricting articles. Covering the wound with a clean sterile cloth will prevent risks of infection and is sufficient during transfer to the nearest emergency center. If possible, burn wounds can be externally applied with medical coolants. The areas of the body that are unburned need to be covered in order to prevent systemic hypothermia.

BURN CARE IN THE EMERGENCY DEPARTMENT

Treatment protocol: Remove all clothing immediately. Areas exposed to the source of burns should be washed with water at 20–25°C temperature to avoid hypothermia. This is continued for a period of 60 minutes. Do not expose the surface to any neutralizing agents, as they may further increase the chances of reaction either directly or by the generated heat. These will cause deepening of burns.

Chemical powder should be initially brushed off with a sterile and clean brush or dry cloth. Once the exposed area is devoid of irritant particles, it is irrigated generously with running water. The applications which should be attempted in the emergency department are summarized below:

Circulation, Airway, and Breathing

A burn patient is treated as any trauma patient. Treatment guidelines should be followed as per advanced trauma life support (ATLS) protocol. Primarily, endotracheal intubation should be done where it is suspected or needed. In a worst-case scenario, tracheostomy must be done to secure airway at the earliest and ensure oxygen supply.

Establish an Intravenous Access

In cases of larger surface area burns, it is imperative to secure a "central" catheterization. It is better to access the subclavian vein than the femoral vein. The same norm holds good for children where one or two peripheral intravenous lines are established.

If the burn wound is extensive involving the central catheterization designated sites as mentioned, then it is mandated to introduce the catheter through the burn wound with the obvious risk of infection in mind but the only parameter that can tide over the crisis is adequate resuscitation and hence this has to be performed after thorough deliberation by the treating doctor. *In children younger than 6 years of age*, if central catheterization is difficult, a 16–18-gauge needle (spinal needle is compatible) is approached from the distal femoral or proximal tibial bone marrow under local anesthesia. Precise and careful attention should be paid to the epiphysis plaque. Intravenous fluid can be initiated at 100 mL/h. During this, other sites for peripheral access can be established by other medical emergency department (ED) personnel.

Avoid Systemic Hypothermia

In order to prevent this, intravenous fluids need to be administered at temperature closer to body temperature.

Polytrauma

In a higher percentage of burns, the victim is likely to endure other injuries, in some cases due to subsequent fall or trauma associated with the event. Serial examinations of upper and lower limbs, along with traumatic brain injury, must be carried out. If any concomitant injury is present, the designated department should be involved. A burns surgeon needs to be followed up with for management of burns. *Ocular injury*: Both eyes are irrigated well to remove all irritants, dust, and debris. The ophthalmologist is consulted for further treatment.

Maintaining Analgesia for the Burns Patient

- Exposed areas are kept under running water for both pain relief and also because it prevents further heat to be dissipated to the underlying tissues.
- In order to prevent hypothermia, the patient needs to be covered well even in unburnt areas. Avoid using ice coolants for local application.
- Pain relief is administered immediately to relieve anxiety and stress. Intravenous administration is preferred due to vasoconstriction as compared to intramuscular or subcutaneous routes (**Box 1**).
- Steady increments of morphine on an hourly basis are preferred to establish the most preferred method of pain relief. In a patient with associated respiratory injury, opioids can only be used with close monitoring of ventilation.
- Careful and precise titration of drugs on infusion should be done. One must look out for respiratory and hemodynamic changes.
- In order to perform escharotomy/fasciotomy, it is done ideally in the burns center. Analgesics such as tramadol and ketamine are most used in these surgical approaches.
- General anesthesia is preferred for children or stressed adults for surgical interventions.

Fluid Resuscitation

This should be initiated based on the total burned surface area involved, >10% in children and >20% in adults. Fluid administration is a crucial effort in recovering the depleted fluid loss in tissues and muscles. **Figure 3** is of paramount importance. It is Jackson's Thermal Wound Theory which comprises three zones of a burn wound signifying three regions with a Zone of Coagulation at the Center which is the tissue that cannot be rescued; following it concentrically in a circumferential manner is the Zone of Stasis and Zone of Hyperemia that can be salvaged. The Zone of Stasis is the tipping point between these two zones; if the dimension of this zone is not maintained then the Zone of Coagulation will encroach on it, whereas if the dimension of the stasis zone is not just maintained but expanded, then the stasis zone expands and undergoes a transition into the Zone of Hyperemia which

BOX 1: Pain management in a burn patient.

- *Analgesics for acute pain relief (intravenous dosage)*:
  - *Tramadol (>12 years of age)*: Every 4–6 h a dose of 1 mg/kg
  - *Ketamine*: Every 15–25 min a dose of 0.2–0.5 mg/kg
  - *Morphine or diamorphine*: Every 4–6 h a dose of 0.03–0.1 mg/kg
  - *Child*: Every 4–6 h a dose of 0.1 mg/kg
  - *Fentanyl*: Every 45–60 min a dose of 1–1.5 µg/kg
  - *Child*: Every 45–60 min a dose of 1 µg/kg
  - *Meperidine*: Every 2–4 h a dose of 0.5–1 mg/kg
- *Suggested combinations therapy for pain management*:
  - *Adults/children*: Combination of fentanyl 0.5–1 µg/kg/h and midazolam 0.03 mg/kg/h is preferred
  - *Children (<12 years age)*: Slow intravenous dose of ketamine at 0.5 mg/kg and fentanyl 1 µg/kg/h infusion is ideal
  - *Children (>12 years age)*: Appropriate dose of ketamine 0.5 mg/kg slow intravenous + tramadol 100 mg/2–4 h infusion
  - *Adults with unstable respiration*: A slow delivery of ketamine 0.5 mg/kg is followed by infusion of tramadol 100–150 mg/2–4 h during transportation

Repeat of doses should be maintained at a 15–20-min interval prior to the end of analgesic time.

- *Outpatient analgesics to be prescribed*:
  - *Children*: Paracetamol (preferably syrup, per oral)—10–15 mg/kg
  - *Ibuprofen*: (>2 years age, per oral) 20 mg/kg/day for 3–4 times a day
  - *Adult*: NSAIDs such as naproxen, oxicam group are preferred

(NSAID: nonsteroidal anti-inflammatory drug)

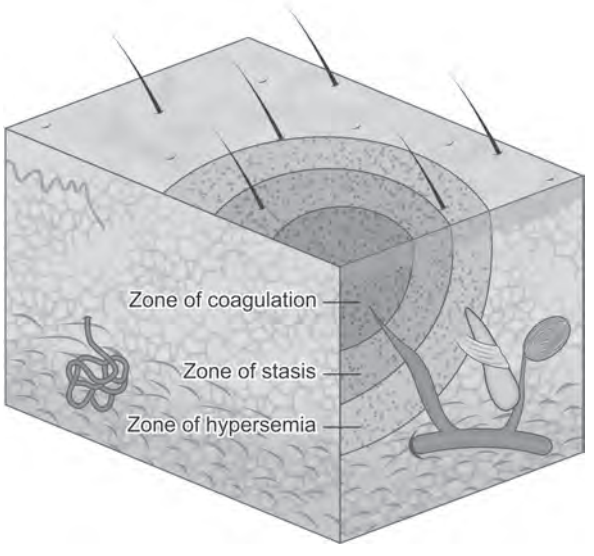


FIG. 3: Three zones of burn wound.

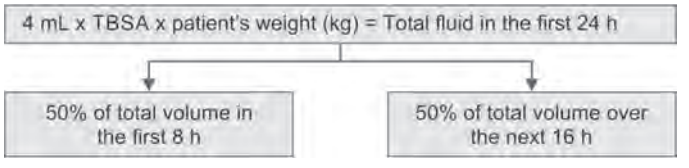
is the requirement in any burn wound. The only parameter that can keep a check on the limits of the Zone of Stasis to remain static is resuscitation and the only parameter that can expand the Zone of Stasis into the required Zone of Hyperemia is

TABLE 2: Pathophysiologic changes in three zones of burn wound.

Zone of coagulation	• Early protein denaturation • Irreversible destruction of protein architecture • Coagulation
Zone of stasis	• Compromised cells • Progressively impaired circulation • Can convert to full cellular necrosis • Platelet microthrombus • Neutrophil adherence to vessel wall • Fibrin deposition • Vasoconstriction • Endothelial edema • Occurs from 2–48 hours' postburn • Recovers in 1 week under optimal conditions • Will still have extensive epithelial cell loss • Tissue tenuous, susceptible to additional insult (dehydration, pressure, hypovolemia, over-resuscitation, infection)
Zone of hyperemia	• Minimal cellular injury • Prominent vasodilation (due to vasoactive mediators from the inflammatory response) • Complete cellular recovery



4 mL x TBSA x patient's weight (kg) = Total fluid in the first 24 h
50% of total volume in the first 8 h
50% of total volume over the next 16 h

(TBSA: total body surface area)

FLOWCHART 2: Distribution of adequate fluid resuscitation over 24 hours.

adequate resuscitation. This is the reason resuscitation takes precedence in burn management (**Table 2**).

The following formulas are recommending guidelines, for estimating the fluid requirement in a burn patient; however, fluid therapy can be modified according to the condition of the patient and prognosis of the injuries.

Adult: Fluid requirement is calculated for the initial 24 hours from the onset of burns by the Parkland formula given below and total fluid is given over 24 hours as shown in **Flowchart 2**.

Parkland formula: Lactated Ringer's solution, 4 mL/kg of body weight × % TBSA

Modified Brooke's formula: 2 mL/kg of body weight/% TBSA

Children: Based on the weight of the child, fluid to be administered using the *Galveston formula* is = 2,000 mL/m^2 body surface area + 5,000 mL/m^2 of TBSA (Ringer's lactate solution).

Special emphasis on the Parkland formula: This is the formula that is being used widely by all the medical personnel, be it resuscitation on the scene of the incident by the paramedics

or by the doctors at the emergency room (ER) once the patient is received. The formula has gained popularity for its simplicity and feasibility making it easy to calculate resuscitation rates. This was a formula devised by Dr Charles F Baxter during his tenure at the Parkland Memorial Hospital. He was one of the doctors at the trauma department who unsuccessfully tried to save the US President John F Kennedy after he was shot in Dallas, Texas, in 1963. It is pertinent to know that the new ATLS guidelines for Parkland formula have a change in the numerical corresponding to the Ringer's lactate. This discrepancy has been mentioned in **Table 3**. The decision on the transition to the new formula is widely accepted by many, but burn specialists believe of falling back on to the old formula, especially if the patient has arrived at the ER with a delay after the burn injury or the patient has been bought early but has not received any fluids in transit to the ER. Otherwise, the new ATLS formula holds well if the resuscitation has commenced within minutes of the incident or has been instituted by a paramedic at the scene of the incident. As this has been a conflict of interest, the author has left the decision to the reader to follow the old/new guideline based on the protocol of the department that he/she is working in.

In certain cases of associated injuries, fluid administration must be increased based on associated injuries. For example:

- Patient under the influence of alcohol or recreational drugs
- *Associated injuries to limbs or viscera*: These may lead to muscle breakdown further adding on to the fluid demand
- Injuries due to inhalational burns
- Delayed onset of resuscitation or signs of dehydration
- Electrical burns

In cases of a larger surface area of burns and/ perineal burns, urinary catheterization is an essential indicator of urinary output. Urinary output should be maintained at a target of 30–50 mL/h in adults and of 1–2 mL/kg/h in children. Urinary density is to be at 1015.

Note: *Inhalational and electrical injuries*—The targeted urinary output should be two-fold the values mentioned above. Local application of creams or pomades for pain relief is contraindicated.

Chemical Burns

The active process of burning continues till the substance is in contact with the surface of the skin. Once completely undressed, the patient is placed under running water at body temperature. Avoid placing the patient in a tub, as this may cause hypothermia. Some chemical burn agents are as follows:

- *Dry lime burns*: Initially, the chemical agent is brushed off and then placed under running water at body temperature.
- *Mercury compounds*: Unroofing of blisters containing mercury is done.
- *Tar burns*: Apply ice cubes on the tarred surface for 10–20 minutes. Tar forms a crusty layer and that eventually peels off.
- *Hydrofluoric acid*: It damages the epidermis of the skin and penetrates into the underlying tissues till it reaches the bone. Even small burns like 10% may be fatal. Hypocalcemia may cause derangement in cardiac activity. Treatment is to apply calcium gluconate gel over the affected area immediately and administration of calcium gluconate intravenously is indicated.

Radiation Burns

High radiation (8–10 Gy of radiation) causes injuries that prolong from few days to few weeks, unlike thermal burn injuries. Pain is usually intractable and progressive in nature.

Investigations

In cases of extensive burns involving a larger TBSA, chemical substance burns and/or electrical burns, it is evident that the patient requires to be admitted in a tertiary burn care center. Arterial blood gas analysis along with serum electrolytes is essential to rule out early signs of metabolic imbalance. Further, serial ECGs and cardiac monitoring should be done, in order to detect preventricular complexes and arrhythmias. In the early minutes of arrival in the ER, it is expected to administer 50 g of mannitol and two ampoules of sodium bicarbonate intravenously. In low-voltage electrical burns, atrial fibrillation with high ventricular response is the most encountered rhythm disorder and cause of death. Therefore, every patient with an electrical burn should have an ECG test. Cardiac monitoring and, if possible, serum creatine phosphokinase-myocardial band (CPK-MB) testing are indicated. Cardiac muscle necrosis may occur, especially in a high-voltage injury, and troponin-1 levels should be examined. If the electric flow trace crosses the heart, 24-hour cardiac monitoring is indicated. Circulation disorder or severe muscle damage may occur in the extremities. Developing edema can cause compression of the muscles and necrosis (compartment syndrome). In such a case, escharotomy is insufficient and fasciotomy is indicated (**Table 4**).

Systemic Examination and Supportive Therapy

Strong contraction of electricity may result in muscle avulsion or shearing. Bone fractures or joint dislocations may be seen. Intra-abdominal visceral damage may also occur. Progressive development of edema and/or eschar tissue formation is present in most cases of larger TBSA burns. Therefore, careful inspection of thorax, abdomen, extremities, and neck should be done, in order to anticipate the need for escharotomy or

TABLE 3: Fluid resuscitation in thermal and electric burn.

	Thermal burns		***Electrical burns***	
	Old ATLS	***New ATLS***	***Old ATLS***	***New ATLS***
Adult	TBSA: % × 4 mL × Weight (kg)	TBSA: % × 2 mL × weight (kg)	TBSA: % × 7 mL × weight (kg)	TBSA: % × 4 mL × weight (kg)
Child	TBSA: % × 4 mL × Weight (kg)	TBSA: % × 3 mL × weight (kg)	TBSA: % × 4 mL × weight (kg)	TBSA: % × 4 mL × weight (kg)

(ATLS: advanced trauma life support; TBSA: total body surface area)

TABLE 4: Surgical procedures of escharotomy and fasciotomy in burns.

Points	*Escharotomy*	*Fasciotomy*
Depth of surgical intervention	Superficial	Deep
Most commonly in	Common in thermal burns	Common in high-voltage electrical burns/other trauma
Intervention relieves	Extrinsic compression	Intrinsic compression
Indications	Circumferential/ near circumferential burns	Brawny edema on palpation
	Signs of impaired perfusion in parts distal to eschar	Signs of impaired perfusion even proximally
Treatment	Anesthesia—not required	Underappropriate anesthesia
	Up to subcutaneous tissue	Through the deep fascia
	Incision on neutral lines	Incision based on compartments

fasciotomy. In cases with >30% TBSA along with a decreased level of consciousness, there is an increased risk of paralytic ileus and gastroparesis. This indicates the need of nasogastric decompression when necessary. Treatment with a H2 receptor antagonist as prophylaxis for acute mucosal lesion is started. In children with good oral tolerance, there is no requirement to start on enteral (EN) nutrition.

Moderate or large TBSA burns: These patients along with a comorbid medical condition need to be evaluated at the earliest. Investigations such as complete blood count (CBC), blood glucose, serum electrolytes, renal function test, liver function test, CPK-MB, and urine for myoglobinuria and/ hemoglobinuria need to be done. Imaging is required in case of deformities, dislocations, or tenderness at joints in order to determine fractures. In case of extensive burns (>30% TBSA), prophylaxis for deep vein thrombosis is started with heparin or low-molecular-weight heparin. General tetanus prophylaxis protocols need to be carried out for all patients.

NUTRITION IN BURNS

Burns is a state of stress of causing a hypermetabolic response. Hypermetabolism means there is a heightened state in the levels of catecholamine, cortisol, and other glucocorticoids concomitant of adrenaline and noradrenaline. This hypermetabolic state lasts 9–12 months after a burn and it alters the metabolism of carbohydrates, proteins, and lipids; hence, knowledge of the same and the supplementation required are essential to be borne in mind while treating the burnt patient.

Glucose metabolism: Hypermetabolism translates its effects on glucose metabolism. The burn have implications on glucose metabolism with accelerated gluconeogenesis from alanine and other amino acids, there is an increase in glucose oxidation and plasma clearance of glucose. The blood glucose levels increase due to insulin resistance and breakdown of glycogen stores and simultaneously glucagon excretion by the liver increases initially after the burn and slows down as the wound heals. Carbohydrates are good sources for protein sparing, especially for nitrogen retention. High carbohydrates can contribute to hyperglycemia in which case a diet can be altered to increase fat in the diet. Recommended 60% of the calories should be from carbohydrates, not surpassing 400 g/day or 1,600 kcal/day.

Protein metabolism: Protein catabolism increases in burn patients leading to protein losses of 260 mg protein/kg/h. The basic unit of proteins being the amino acids, it is quintessential for collagen synthesis and in turn for wound healing, hence mandating a 1.4–2.2 g/kg protein requirement for burns. This exogenous protein intake is important for maintaining visceral protein for organ function, especially for immune systems and also for the muscle mass of the diaphragm and intercostal muscles for adequate respiratory efficiency. It is to be borne in mind that any trauma patient may lose 20–25 g of lean body nitrogen daily and this loss is exponential as a urinary nitrogen loss in patients with burn injury. So, keeping these losses in mind, the protein requirement estimate is calculated by combining 24-hour urinary nitrogen loss, 2–4 g of nitrogen for fecal loss, and 45 g/day for anabolism. Convert each gram of nitrogen to 6.25 g of protein. Patients are likely to miss feedings if in surgery frequently, so they should be given high-protein formulas between surgeries. Be aware of uremia—increase the free water intake. Generally, 20–25% of calories are derived from protein.

Lipid metabolism: Lipid stores are critical for long-term fuel after major thermal burns; fat oxidation is higher in hypermetabolic patients than in normal patients. Fat consumption should not exceed 30% of the diet to avoid diarrhea. Lipid intake is beneficial because fat is a more concentrated form of energy; lipid is available in the form of vegetable oil and contain essential fatty acids and fat-soluble vitamins. It is recommended that 12–15% of calories should be lipids.

Types of Nutrition Therapy in Burns

Oral: The first step in assessing nutrition care is to determine if oral care is appropriate. Natural digestion is preserved when eating orally. Consuming food provides micro- and macronutrients as well as phytochemicals and antioxidants. Nutrients and phytochemicals from food aid in wound healing and overall health of the patient.

Enteral: EN feeding is initiated when 80% of caloric and protein needs cannot be met. An appropriate step may be to administer night feedings so that appetite and oral intake during the day can be stimulated. Early administration of a feeding tube has shown positive effects on wound healing and diminishing gut bacterial translocation.

Parenteral (PN)*:* PN feeding is administered via the modality known as total parenteral nutrition (TPN) which is the last option for nutritional support. If no other means is acceptable, TPN may be administered. The characteristic features of oral, enteral, and parenteral modes of nutrition are given in **Table 5**.

Because of hypermetabolism and being in a high-stress state, burn victims need higher energy requirements (**Table 6**). The Harris–Benedict equation is an option to use

which takes into account stress factors and the percentage of burns. Use of the modified *Harris–Benedict equation* to estimate resting energy expenditure: BEE = (66.47 + 13.75 W + 5.0 H-6.76 A) × (Activity Factor) × (Injury and/or Burn Factor)

W = Weight in kg, H = Height in cm, A = Age in years.

WOUND CARE

In cases of TBSA < 10%, an outpatient criterion can be applied after the initial observation. The need for intravenous fluid resuscitation and ongoing complications must be dissolute. Early signs of sepsis should not be missed out. Maintenance of adequate oral nutrition and oral analgesics for pain relief must be taken into account. The wound should be rinsed with tap water or saline solution in order to get rid of debris or foreign body, except for neutral pH liquid. Adequate dressing with paraffin or ointment like nitrofurazone 0.2% should be carried out under sterile conditions. In cases of evident infection, eschar or larger TBSA, application of 1% silver sulfadiazine is done. However, in the presence of epithelialization, silver-containing agents should not be applied as these delay epithelialization.

Apart from face burns, 1% silver sulfadiazine is applied on burn wounds generously (**Table 7**).

TABLE 5: Choosing modes of nutritional therapy in a burn patient.

Oral	*Enteral*	*Parenteral*
Preserves GI function	Ryle's tube insertion	Total parenteral nutrition
Food has therapeutic qualities that tube feedings do not	Prevents bacterial translocation from the bowel	IV access required may predispose to infection

INDICATIONS OF HOSPITALIZATION FOR A BURN PATIENT

- *Second- and third-degree burns*: TBSA > 20% at all ages
- *Third-degree burns*: TBSA > 20% at all ages
- Second- and third-degree burns, with TBSA ≥ 10% in patients younger than 10 years or older than 50 years of age
- Burns over the face, ear, hand, and foot, including major joints, genitalia, and perineum
- Inhalation injuries, chemical burns
- Electrical burns, lightning strike
- *Polytrauma*: Associated orthopedic injuries, cardiac arrhythmias, traumatic brain injury
- *Pregnancy*: Monitor fetal heart rate and uterine activity
- Suspicion of child abuse
- *Long-standing co-morbid conditions*: Coronary artery disease, hypertension, diabetes mellitus, neurological ailments

The above mentioned are a spectrum of cases requiring immediate evaluation. However, if in any doubt, an emergency physician should consider the hospitalization of a patient based on the progression and prognosis of burns.

TABLE 6: Nutritional requirements in a burn patient.

Calories	*60% Carbohydrate*	*20–25% Protein*	*12–15% Lipids*	
Vitamins	*Vit C*: 1,000 mg/day orally	*Vit A*: 10,000 IU/day orally	• *Vitamin D*: 200–400 IU/day • Ca^{2+}: 1,000 mg daily orally	*Vitamin E*: 100 mg/day orally
Trace elements route—IV	*Copper*: 2.5–3.1 mg/day	*Selenium*: 315–380 µg/day	*Zinc*: 26.2–31.4 mg/day	• *1 week*: 20–40% TBSA • *2 weeks*: 40–60% TBSA • *4 weeks*: >60% TBSA

(TBSA: total body surface area)

TABLE 7: Wound care in burns.

First-degree burns	*Second-degree burns*	*Third- and fourth-degree burns*
• *Dressing/antibacterial agents*: Not required • Ointment/creams for local application are sufficient. These decrease local inflammation • Oral analgesics is prescribed for 5–7 days • Larger first-degree burns require hospitalization in order to administer fluid intravenously and pain relief	• *Superficial burns*: ○ Aseptic dressing with paraffin and woven fabrics ensure that the wound does not stick to the dressing ○ Use of polyurethane film sheets ± ○ In other cases, aseptic and clean wound dressing is done with paraffin or 0.2% nitrofurazone impregnated gauze • *Blister management*: Smaller blisters may be left intact whereas larger blisters need unroofing to be done, followed by serial dressings and follow-up: ○ *Deep burns*: Application of silver sulfadiazine, mupirocin, and nitrofurazone over the burns directly or underneath the gauze along with paraffin is mandatory • *Signs of delayed wound healing*: Increased risk of hypertrophic scar formation, keloid, discoloration, and contractures is present. Hence, the patient needs to be referred to a tertiary burn care center	• *Full-thickness burn*: Spontaneous eschar separation does not occur. Infection causes the eschar to separate spontaneously, due to the enzymatic products of bacterial growth • These types of burns require transfer to a burns unit for further surgical intervention

INHALATION INJURY: EARLY DIAGNOSIS AND TREATMENT

Inhalational injury comprises three different injuries caused by thermal and/or chemical irritants:

1. *Chemical injury*: Affects the whole respiratory system.
2. *Thermal injury*: Affects primarily the upper respiratory system.
3. Toxic inhalation of smoke; during indoor burn cases, inhalation of carbon monoxide or cyanide. These lead to spread of toxic irritants into systemic circulation. Extensive inhalational injuries can present even in the absence of skin burns.

Clinical Manifestations

- Decreased consciousness of patient, cyanosis, and burns over hair, face, ear, and nose is present.
- Voice hoarseness, mucosal edema, black sputum, and presence of carbon particles are present in mucosa.
- Neck burns present circumferentially along with perioral and facial burns.
- *Carbon monoxide intoxication*: Nausea, fatigue, dizziness, headache, chest pain, palpitations, visual disturbances, pain in abdomen, and disoriented mental status.

Management

- Remove the patient from the scene and decontaminate him/her.
- Maintenance of securing airway for position, insertion of airway, and prevention of tongue's backsliding.
- Support breathing with nasal cannulation/high-flow oxygen mask or endotracheal intubation in patients with apnea and/or obstructive breathing.
- Assessment of circulation by adequate fluid resuscitation, correction of electrolyte imbalance, warming, and support for the cardiopulmonary system are requirements.
- Oxygen support of 100% on high flow (7–8 L/min) via a nasal cannula or mask should be initiated.
- Mechanical ventilation/endotracheal intubation is indicated in patients with circumferential neck burns, perioral burns, facial burns, decreased level of consciousness, subglottic edema, or progressive hoarseness.

CRITERIA FOR REFERRAL TO A BURN UNIT/ SPECIALIST

There are two ways to transfer a patient: one is from the scene to a hospital and the other is from one hospital to a burns tertiary care hospital. *Red flags*: One must be aware of the likelihood of progression of the condition of the patient to a life-threatening situation during transport. With a potential to survive, there should be no delay in transport of the patient to the nearest healthcare facility within the vicinity. Patient referral depends on two golden rules: (1) Adequate communication and (2) fruitful teamwork. The following must be taken into consideration prior to transfer of the patient to another hospital: Initial stabilization of vital hemodynamic must be done. The referral hospital must be well informed about the condition of the patient. Adequate information should be communicated between healthcare physicians at the referral hospital and the current hospital. Adequate information of the patient includes age/gender of the patient, time of the accident, place of the accident, mode of injury, clear description of injuries (% of TBSA), weight/height of the patient, vital medical history of the patient along with laboratory results, neurological status, and medical attention provided to the patient immediately after the accident. Verbal as well as written documentation provides a representation of the overall condition and prognosis of the patient.

Checklist prior to transfer of patient: A—airway, B—breathing, C—circulation should be adequately secured and monitored. As mentioned above in management, transfer of the patient with unstable vitals is not a priority. Initial stabilization plays a higher hand at survival than transfer to a burns facility with a possibility of cardiac arrest en route. It is needless to say that during transfer and in view of a decreased neurological status, it is essential to secure the airway through intubation or to perform a tracheostomy and maintained over ventilator support:

- Two large venous catheters are established, preferably in the upper extremities.
- During transit, one must ensure that urinary catheterization is done prior to transfer. Maintain a urinary output for adults at 30 mL/h and children at 1 mL/kg/h.
- The patient should be discouraged of oral intake and a Ryle's tube is inserted in patients with burned TBSA >30%. Enteral nutrition should be initiated early in the stabilization of the patient and maintained at 10 mL/h infusion and may be increased as per patient tolerance.
- Lactated Ringer's solution is the fluid of choice in the initial 24 hours of burns prior to transfer. The amount of fluid to be administered is decided by the treating physician. In children, Ringer's lactate solution with dextrose is preferred.
- Cardiac monitoring (ECG) and respiratory status are to be monitored.
- Wet dressings should be avoided at all cost.
- The patient should be covered (even at unburned areas) in order to prevent hypothermia.
- Specialist referral is indicated as per **Table 8**.

MEDICOLEGAL INSIGHTS AND CHILD ABUSE

Burn patients need to be evaluated forensically. In patients with a high risk of mortality, injuries suspicious of nonaccidental purpose should be carefully investigated on the basis of the history of the accident and reported to respective authorities. In case of situations where the patient or relatives of the patient deny medical attention, medical care cannot be initiated. In the event of such a scenario, a detailed consent form should be duly signed by the patient as well as two witnesses against a probable risk of medical negligence. The patient and family members need to be acquainted of the possible risks of denying medical advice. They should provide a signed statement of agreeing to have read and understood the risks involved in denying medical attention. The consent of parents

TABLE 8: Referral of a burn patient to a specialist.

High index of suspicion	*Investigations to be acquired prior to the specialist's visit*	*Referral specialist*
Smoke inhalation injury	Chest X-ray	Pulmonologist
Facial burns, to rule out any corneal injury	Fluorescein stain	Ophthalmologist
Cardiac disease/ electrical burns	• ECG • 2D ECHO to be mobilized	Cardiologist
Diabetes mellitus	• Random blood sugar (RBS) • Estimated average glucose (eAG) • Glycosylated hemoglobin (HbA1c)	Endocrinologist
Associated skeletal injuries	X-ray trauma series	Orthopedic surgeon
Associated head injuries	Plain CT scan of the head	Neurosurgeon
Limb threatening, compartment syndrome, burn wounds on the chest, and a resultant decreased chest expansion	• Appropriate dressing materials based on the depth of the wounds and surface area of the burns • In an event of electrical burns, markers for rhabdomyolysis	Plastic and reconstructive surgeon

or legal guardian should be taken in view of medical care to be provided for children (**Fig. 4**). The legal guardian or parents have the legal right to deny any medical care to the patient. A written consent signed by the parents/legal custodian is taken. In case of a request for help, it should be availed. In the event of a nonaccidental injury (NAI), with a suspicious medical history, it becomes clearly evident of child abuse.

Possible Signs of Abuse in Burn Cases

- Delay in availing medical attention and seeking help from the nearest hospital
- Different scenarios of accident explained at the time of admission to a hospital
- Incongruity between clinical manifestations and history provided from family members
- Blaming the accident on another sibling or relative by the parents or legal guardian
- Parent/legal guardian expressing unruly behavior or violent actions
- Unpleasant or abnormal appearance of child
- Deranged relationship between the child and the parents
- Child should be taken into a secure environment and asked about the detailed events leading to the accident. This can be very helpful in finding out the cause and criminal of accident
- Past history provided in which the child has been treated at different hospitals at multiple situations
- Accusation by child directly on parents about the accident caused
- Highly irrelative/illogical expectation by the parents on the child.

FIG. 4: Scalds due to accidental outpour of hot milk over the lower half of the face, chest, and abdomen. ***(For color version, see plate 51)***

Possible Findings on Medical Examination

- *Indications of punishment*: Discoloration, ecchymosis on upper and lower limbs, genitals, back
- Injuries with varied stages of healing
- Blunt trauma causing liver/spleen rupture
- Cigarette burns or hot water burns (scalds) on the hands, feet, perineum
- Subdural hematoma (chronic signs) with or without damage to cranium
- Signs showing metaphysic decomposition, calcifications, periosteal bleed

Tell-tale Signs of Child Abuse

- Child is oversensitive or insensitive to painful stimulus.
- Manifestations of the clinical condition of the child are much before the proposed time of the accident.
- Varied degrees of burns and incisions are present closely.
- Covering up of lesions/injuries with clothing (scarf, jacket).
- Unusual locations of injuries such as tongue, lip, and frenulum.

PROGNOSTIGATION OF THE BURN PATIENT

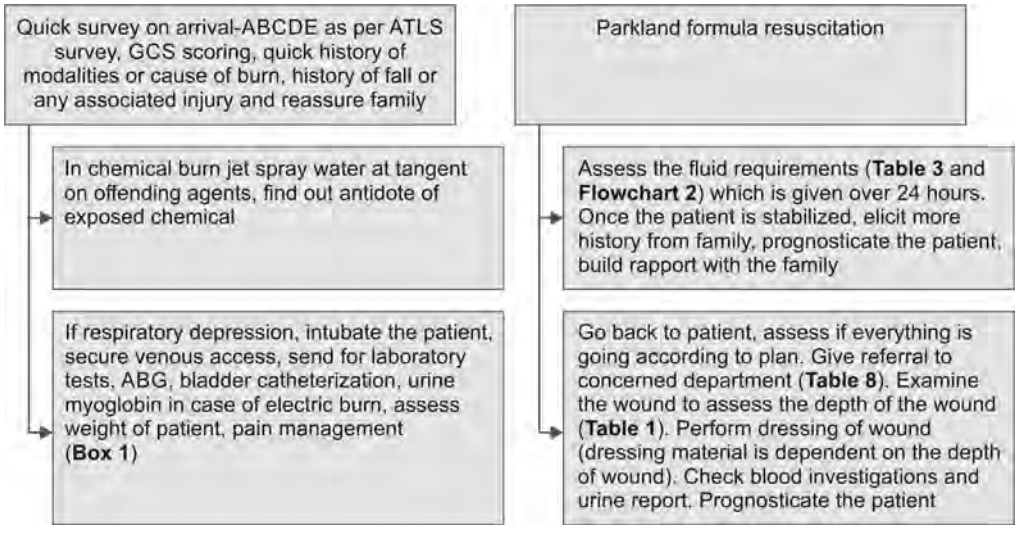
Once the patient is stabilized, speak to the bystanders and prognosticate them of the resuscitative efforts being done and elicit more history on how the fire was doused, history of comorbidities, and past history of medications/surgeries and personal history. Build a rapport with the attenders. Get back to the patient to check if everything is going in accordance as planned. Check arterial blood gas (ABG). Check blood reports and urine reports. Prognosticate the patient by keeping the following points in mind:

- Natural history of the disease
- Complicating events
- Further treatment required

- Referral required or not
- Treatment cost
- The need for an intensive care unit (ICU) stay
- Surgical interventions required
- Morbidity and mortality
- High-risk consent documentation
- Guarded prognosis documentation
- The possibility of postburn contractures and the management required for its prevention and surgical management by a plastic and reconstructive surgeon.

SUMMARY

Burns are associated with significant morbidity and mortality. Burns affect the people of productive age groups and are the only form of trauma where the incidence is more in females. Most of the risk factors for burn injuries are preventable and the mortality and morbidity can be minimized with proper care. An emergency physician should be well aware of the structured plan for managing the burn patients in the emergency department (**Fig. 5**).



Quick survey on arrival-ABCDE as per ATLS survey, GCS scoring, quick history of modalities or cause of burn, history of fall or any associated injury and reassure family
Parkland formula resuscitation
In chemical burn jet spray water at tangent on offending agents, find out antidote of exposed chemical
Assess the fluid requirements (Table 3 and Flowchart 2) which is given over 24 hours. Once the patient is stabilized, elicit more history from family, prognosticate the patient, build rapport with the family
If respiratory depression, intubate the patient, secure venous access, send for laboratory tests, ABG, bladder catheterization, urine myoglobin in case of electric burn, assess weight of patient, pain management (Box 1)
Go back to patient, assess if everything is going according to plan. Give referral to concerned department (Table 8). Examine the wound to assess the depth of the wound (Table 1). Perform dressing of wound (dressing material is dependent on the depth of wound). Check blood investigations and urine report. Prognosticate the patient

CHAPTER

Accidental Hypothermia

Rahul Solanki

INTRODUCTION

Accidental hypothermia (HT) is an unintentional drop in core temperature to 35°C or below. It can be caused by environmental exposure or by decrease or conditions that decrease thermodynamic responses. Resuscitation in emergency can lead to iatrogenic accidental HT. Accidental HT can occur in people who were outdoor for recreational activities or in homeless people. It can occur in any climate (tropical or subtropical) or during any season. Trauma, sepsis, and diseases that decrease metabolic heat production or affect thermoregulation are presented in **Table 1**.

PATHOPHYSIOLOGY

Resting metabolism and neurological functions are decreased as a result of cooling. Even when the core temperature is normal, skin cooling induces shivering which directly increases metabolism by increased muscle activity and indirectly by increased ventilation and cardiac output. As core temperature decreases shivering increases and reaches at maximum level when core temperature is about 32°C and stops by about 30°C. With decreasing temperature metabolism generally decreases below 32°C.

CLINICAL FEATURES AND CLASSIFICATION

The clinical effects of HT are because of decreased function of brain and cardiorespiratory system (**Table 2**). Function of brain is impaired by cooling, which begins at about 34°C and worsens with further cooling. Clinical signs are confusion, irritability, apathy, poor decision making, somnolence, lethargy, coma, and death. Except death, most of the changes are reversible. Even patients in coma often recover neurologically intact. Cold brain has decreased metabolic requirements which can be neuroprotective, especially during anoxic conditions, e.g., drowning. Circulating blood volume is decreased because of cold-induced diuresis, plasma leak, and decreased fluid intake. There is bradycardia and decreased cardiac output because of cooling of heart. Atrial dysrhythmias and premature ventricular contractions and ventricular fibrillations (VFs) can occur as the heart cools to 30°C or below. Below 28°C, VF can be induced by hypocarbia, acidosis, and hypoxia. There is decreased ventilatory sensitivity to carbon dioxide which can result in hypoventilation and respiratory acidosis.

Swiss System Classification

This system of classification correlates clinical signs with the standard core temperature ranges of mild, moderate, and severe HT as well as two additional stages; profound HT and death due to HT. Stages of HT are:

- *HT I*: Clear consciousness with shivering: 35°C to 32°C
- *HT II*: Impaired consciousness without shivering 32°C to 24°C.
- *HT III*: Unconsciousness: 28°C to 24°C
- *HT IV*: Apparent death: 24°C to 13.7°C
- *HT V*: Death due to irreversible HT: <13.7°C

Patients having moderate HT (HT II) are likely to be shivering if the core temperature is above 30–31°C. Rescuers are advised to focus on the level of consciousness rather than the presence or absence of shivering. Trauma and other medical conditions that cause decreased level of consciousness or abnormal vital signs can lead to confusion while classifying the patients. As these conditions may also suppress or abolish shivering the rescuers may rewarm more aggressively at a given core temperature than would otherwise be necessary.

DIAGNOSIS

Hypothermia should be considered in patients if there is a history of cold exposure or diseases that predisposes them to HT, and if they have a cold trunk or a core temperature of <35°C.

Core Temperature Measurement

Mercury or alcohol-containing thermometers cannot measure temperature <35.6°C. When a nonelectronic thermometer device is used, it must be a low reading thermometer. Oral temperature is used only to rule out HT as the oral temperature is lower than core temperature by a variable amount. Rectal and bladder temperature can lag behind core temperature

TABLE 1: Conditions associated with secondary to hypothermia.

Impaired thermoregulation	*Central failure*: • Anorexia nervosa • Cerebrovascular accident • Central nervous system trauma • Hypothalamic dysfunction • Metabolic failure • Neoplasm • Parkinson's disease • Pharmacologic effects • Subarachnoid hemorrhage • Toxins
	Peripheral failure: • Acute spinal cord transection • Decreased heat production • Neuropathy
	Endocrinologic failure: • Alcoholic or diabetic ketoacidosis • Hypoadrenalism • Hypopituitarism • Lactic acidosis
	Insufficient energy: • Extreme physical exertion • Hypoglycemia • Malnutrition
	Neuromuscular compromise: • Recent birth and advanced age with inactivity • Impaired shivering
Increased heat loss	*Dermatologic disorder*: • Burns • Medications and toxins
	Iatrogenic cause: • Emergency childbirth • Cold infusions • Heat-stroke treatment
	Other associated clinical states: • Carcinomatosis • Cardiopulmonary disease • Major infection (bacterial, viral, and parasitic) • Multisystem trauma • Shock

changes by up to 1 hour. They can give false impression that the patient still cooling during rewarming. Until a patient is in a warm environment rectal or bladder temperature should not be performed as exposing a hypothermic patient causes further heat loss. Rectal probe should be inserted to a depth of 15 cm.

TABLE 2: Signs and symptoms of hypothermia.

System	***Features***		
	Mild (35°C to 32°C)	*Moderate (32°C to 28°C)*	*Severe (<28°C)*
CNS	Amnesia, dysarthria, and impaired judgment	Drowsiness, mydriasis, paradoxical undressing, and hallucinations	Coma and loss of ocular reflexes
CVS	Tachycardia progressing to bradycardia and raised BP	Atrial and ventricular arrhythmias, lowered BP, and J wave on ECG	Severe hypotension, bradycardia and asystole
Respiratory system	Tachypnea followed by decrease in minute volume and bronchospasm	Hypoventilation	Pulmonary edema and apnea
Renal and endocrine systems	Cold diuresis and shivering	Increased renal blood flow	Decreased renal blood flow, oliguria, and poikilothermic
Musculoskeletal system	Increased muscle tone followed by fatiguing and anoxia	Hyporeflexia and rigidity	No motion and peripheral areflexia

(BP: blood pressure; CNS: central nervous system; CVS: cyclic vomiting syndrome; ECG: electrocardiogram)

Esophageal Temperature

It is the most accurate and minimally invasive method of core temperature measurement. The probe should be inserted into the lower third of esophagus (approximately 24 cm below the larynx in adults). At this level of esophagus heated humidified oxygen does not affect esophageal temperature. It is usually preferable to protect airway with endotracheal intubation or supraglottic airway.

Epitympanic Temperature

Epitympanic probes are not accurate in the field settings as they are designed to be used in operating theaters. They can be useful when an esophageal probe is not available. Also used preferably over esophageal probe, if airway of the patient is not protected.

Heat Flux Thermometers

It is a noninvasive method of measuring core temperature in hypothermic patients in and out of hospital. The readings

accurately reflect the core temperature in operative and intensive care units.

MANAGEMENT

Out of Hospital Management

Before evaluating the patient and starting treatment, the patient should be moved to a safer place. Safety of the rescuers is the first priority during the rescue. Rescuers should not enter the scene if a hypothermic patient has an obvious fatal injury. After ensuring their safety, rescuers should determine whether the patient is in cardiac arrest. If there is an indication, rescuers should start resuscitation if the patient is in cardiac arrest. If vital signs are present in a patient but not alert then rescuers are advised to avoid causing cardiovascular collapse handling gently and by keeping the horizontal as much as possible. After removing the patient from the scene, encourage the victim to stay alert and focus on survival to minimize the chance of circumrescue collapse. Rewarming and movement of extremities should be avoided to prevent increased blood flow to cool peripheral tissue with resultant increase in return of cooled blood to central circulation. Carefully check signs of life and pulse for 60 seconds as it may be difficult to detect pulse in a hypothermic patient. All patients should be provided full body insulation and rewarming unless it does not impede cardiopulmonary resuscitation (CPR) or delay transport. Only electrical, chemical, or forced air heating packs or blankets should be used as they provide substantial amount of heat transfer.

Cold Stressed Patient who is not Hypothermic

A patient who is completely alert and shivering, well-nourished, and not hypothermic is not at risk for significant afterdrop and circumrescue collapse. Wet clothing of such patients can be removed. They may eat and drink and ambulate as there is no need to be horizontal. Core temperature afterdrop can contribute to cardiovascular instabilities in patients with moderate-to-severe HT during out of hospital care. In hypothermic patients, afterdrop as high as 5–6°C have been reported.

Circumrescue Collapse

It is syncope or sudden death that occurs in patients of cold-water immersion or after rescue and removal from water. It may be due to sudden hypotension or sudden onset of VF. *Prevent further heat loss*—core temperature should be maintained by providing vapor barrier and by adding insulation. Insulation can be added by extra clothing, blankets, quilts, insulated pads, and sleeping bags. Vapor barriers are bubble wraps, plastic sheets, reflective blankets, and garbage bags. They protect against heat loss from evaporation and convection. After these the patient should be rewarmed. Patients with decreased level of consciousness require active rewarming. Rewarming is not required for mild HT that is not complicated by other conditions. Active rewarming methods are preferred over shivering, because shivering is uncomfortable and can stress cardiovascular system. The patient should be insulated and given high carbohydrate drink and food if active rewarming is not possible. Shivering can increase core temperature by 1–3°C per hour in a well-insulated patient with adequate caloric reserves. Do not allow standing and walking in a hypothermic patient who is found sitting or lying down.

Active external rewarming is beneficial in alert, shivering patient and is mandatory in a patient who has decreased level of consciousness. Rewarming may be provided by using large chemical heat pads, large electrical heat pads or blankets, warm water bottle or Norwegian charcoal-burning HeatPac. Body-to-body rewarming of shivering person in a sleeping bag decreases shivering and does not increase the rate of rewarming.

A warm shower or bath should not be used for rewarming because it can lead to cardiovascular collapse. Vasodilation of skin causes increased afterdrop and decreased blood pressure. Cold skin is very susceptible to injuries from pressure and heat. A barrier should be used to protect the skin when using electrical or chemical heat pads and precautions should be taken against pressure injuries. Heated, humidified oxygen should be provided to prevent respiratory heat loss, but it should not be used alone as a rewarming method.

Cardiopulmonary Resuscitation in Hypothermic Patient

Hypothermia protects the brain from hypoxia by reducing brain activity. If core temperature is 20–28°C or not known, rescuers should perform CPR continuously for 5 or more minutes and limit interruptions to CPR to 5 minutes or less. If the core temperature is 20°C or below, CPR should be continued for 5 or more minutes with interruptions of 10 minutes or less. There is no known limit for duration of CPR in a severely hypothermic patient. If there are no contraindications to CPR, rescuers should attempt to resuscitate a patient with severe HT regardless of the measured core temperature. One must remember that low core temperature should not limit resuscitation.

Defibrillation in Hypothermic Patients

Rescuers should wait until a patient has been rewarmed at least 1–2°C before reattempting defibrillation. Above a core temperature of 30°C one should follow usual defibrillation protocol.

The guidelines of European Resuscitation Council recommend a modified approach to Advanced Life Support (ALS), consisting of up to three defibrillations with epinephrine withheld until the core temperature is higher than 30° (86°F) and with the interval between doses doubled until the core temperature is higher than 35°C (95°F). These recommendations conflict with the American Heart Association guidelines, which state, "It may be reasonable to consider administration of a vasopressor during cardiac arrest according to the standard ALS algorithm concurrently with the rewarming strategies." Hence, the administration of up to three doses of medication and defibrillation is likely to be a reasonable approach with further dosing guided by the clinical response.

Chest Compression

Rescuers should perform chest compression at the same rate as in a normothermic patient. During transport, use mechanical compression as manual compression is difficult to perform.

Ventilation in hypothermic patient is ineffective unless an advanced airway (endotracheal tube or supraglottic device)

is in place. If there is an advanced airway, ventilation should be at half the usual rate. If there is no advanced airway end-tidal CO_2 ($EtCO_2$) monitoring is not available, rescuers should administer ventilation to a hypothermic patient at the same rate as for a normothermic patient. Supplemental oxygen may be needed at altitudes above 2,500 m. At sea level, a hypothermic patient may not be hypoxemic. Management of airway is similar in hypothermic and normothermic patient. VF might occur during endotracheal intubation. The risk of VF should not preclude standard airway management with intubation, if indicated. Sometimes trismus prevents laryngoscopy, in that case use of supraglottic device is preferred than fiberoptic intubation or cricothyroidotomy. Cough of an endotracheal tube or supraglottic device should not be over inflated with cold air. Overinflation could cause kinking of the tube or rupture of the cuff if the patient rewarms and the air in the cuff expands. Neuromuscular blockers and anesthetic are likely to be ineffective below 30°C, but their metabolism is decreased and the effects are likely to be prolonged when the agents become effective as the patient rewarms. The dosage of these drugs should be lowered and dosing interval extended.

Fluid Management and Volume Replacement

In a hypothermic patient, intravenous access is difficult due to peripheral vasoconstriction. In such condition intraosseous (IO) access can be used. Central venous access can be used but if the catheter or guidewire comes into contact with the myocardium it may cause VF. In moderate and severe HT blood volume is decreased. Normal saline should be given for volume replacement to prevent hypotension and shock. Ringer lactate should not be used as they cannot metabolize lactate at cold temperature. Insulated tubing and fluid warmer should be used to avoid infusing cold fluid. Fluid should be warm to 40–42°C to avoid cooling or freezing of lines, fluids are best given rapidly as boluses.

Glucose and Insulin Use

In a hypothermic patient either hypoglycemia or hyperglycemia can occur. In a hypothermic patient with altered mental status, glucose is given by IO or intravenous routes. Treatment with insulin is not necessary if there is hyperglycemia in a hypothermic patient and it may not be effective below 30°C. Hyperglycemia has no known adverse effects in HT.

Cardiovascular Drugs

There are not sufficient data for the use of cardiovascular drugs in HT below 30°C. In HT, metabolism of drugs is decreased as protein binding is increased. It is better not to give vasoactive drugs in a patient with core temperature <30°C. Between 30 and 35°C drug should be given at the normal dose but with twice interval between doses. Atrial dysrhythmias often occur during rewarming and should not be treated if the patient is hemodynamically stable.

Pacing

Transcutaneous pacing may be used in a patient having bradycardia and hose blood pressure is too low to allow arteriovenous rewarming. Transvenous pacing is contraindicated in HT due to cardiac instability.

Transport and Triage

An alert patient with shivering can be treated in the field unless the patient has an injury or medical conditions requiring evacuation. Patient having asphyxia from drowning or avalanche burial are at risk of delayed complications and they should be shifted to a center capable of managing acute respiratory distress syndrome. Severely injured patients should be treated as soon as possible with active rewarming to prevent HT as they are unable to shiver and become hypothermic quickly, even during mild weather. A cold stressed or hypothermic patient with decreased level of consciousness should be treated with activity rewarming even if shivering. A patient with moderate/severe HT who is hemodynamically stable should be transported to nearest center with rewarming facilities. A hemodynamically unstable patient should be transferred to a center that can perform extracorporeal circulation (ECC) using extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass.

Importance of Serum Potassium

High-serum potassium is a marker of cell lysis and death. If hypothermic patient in cardiac arrest has serum potassium >12 mmol/L, CPR should be discontinued as patient can be declared dead without further warming.

Inhospital Management

In a patient with HT and stable circulation active external and minimally invasive rewarming is induced along with treatment of any condition causing secondary HT. Considering the risk of complications such as thrombosis and hemorrhage with rewarming methods (e.g., body cavity lavage, endovascular device, and extracorporeal heating system), the best approach may be the use of active external and minimally invasive rewarming. ECMO or cardiopulmonary bypass should be considered for patient with HT and cardiac instability who are not responding to medical management.

Treatment with ECMO and cardiopulmonary bypass is safe and efficient when signs of life and vital signs are absent (stage HT IV). After rewarming there are chances of developing severe pulmonary edema. It can be treated more efficiently with ECMO compared to traditional cardiopulmonary bypass.

If a patient with cardiac arrest due to HT is rewarmed to a core body temperature that is >32°C and asystole persists, irreversible cardiac arrest is very likely and termination of CPR should be considered. Staging-based management of accidental HT is summarized in **Table 3**.

HYPOTHERMIA OF EXTREMITIES

Frostnip and Chilblain (Erythema Pernio)

Frostnip is a temporary and mild form of cold-induced injury causing local paresthesia of the involved area that completely resolves with passive external rewarming. Chilblains (erythema pernio) are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesion maybe purple or red papular lesions which are painful or pruritic with burning or paresthesia. They may be associated with edema or blistering and aggravated by warmth. If exposure

TABLE 3: Staging and management of accidental hypothermia (HT).

Stage	*Clinical symptoms*	*Typical core temperature*	*Treatment*
HT I	Conscious and shivering	35°C to 32°C	Warm environment and clothing, warm sweet drinks, and active movement (if possible)
HT II	Impaired consciousness and not shivering	<32°C to 28°C	Cardiac monitoring, minimal and cautious movements to avoid arrhythmias, horizontal position and immobilization, full-body insulation, active external and minimally invasive rewarming techniques (warm environment; chemical, electrical, or forced-air heating packs or blankets; warm parenteral fluids)
HT III	Unconscious, not shivering, and vital signs present	<28°C to 24°C	HT II management plus airway management as required; ECMO or CPB in cases with cardiac instability that is refractory to medical management
HT IV	No vital signs	<24°C	HT II and III management plus CPR and up to three doses of epinephrine (at an intravenous or intraosseous dose of 1 mg) and defibrillation, with further dosing guided by clinical response; rewarming with ECMO or CPB (if available) or CPR with active external and alternative internal rewarming

- Hypothermia may be determined clinically on the basis of vital signs with the use of the Swiss staging system. CPB denotes cardiopulmonary bypass, CPR denotes cardiopulmonary resuscitation, and ECMO denotes extracorporeal membrane oxygenation
- Measurement of body core temperature is helpful but not mandatory. The risk of cardiac arrest increases as the core temperature drops below 32°C and increases substantially if the temperature is <28°C. To convert values for temperature to degrees Fahrenheit, multiply by 9/5 and add 32

is continuous, ulcerative or hemorrhagic lesions may appear and progress to scaring, fibrosis, and atrophy.

Treatment

Affected part is kept elevated and passively external rewarming is used. Rubbing and massaging injured tissue is avoided. Applying ice and heat is also avoided. Protect the affected area from trauma secondary infection and further cold exposure.

Immersion Foot or Trench Foot

Immersion foot (or hand) is caused by prolonged immersion in cold water or mud usually below 10°C. It has three stages:

1. *Prehyperemic stage*: Characterized by symptoms of cold and anesthesia
2. *Hyperemic stage*: Hot sensation, severe burning, and shooting pain
3. *Posthyperemic stage*: With ongoing cold exposure the affected part becomes pale or cyanotic with diminished pulsation due to venospasms. This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, and gangrene.

Treatment consists of air drying, protecting extremities from trauma and secondary infection, and gradual rewarming by exposure to room temperature. Avoid using ice or heat. Avoid massaging, moistening of the skin. Affected part can be elevated, cushions are used to protect the pressure sites.

Frostbite

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. With reperfusion of the frozen tissue, destruction occurs with damaged endothelial cell and progressive microvascular thrombosis causing further tissue damage. Only skin and subcutaneous tissue are involved in mild cases. Symptoms are prickling, numbness, itching, and pallor. Deeper structures are involved with increasing severity. The skin appear white or yellow, elasticity is lost and becomes immobile. Edema, hemorrhage blister, necrosis, gangrene, paresthesias, and stiffness may occur.

Treatment

Secondary exposure to cold is avoided. Associated systemic HT, concurrent condition, and injury are evaluated and treated. Fluid is given to avoid hypovolemia and to improve perfusion.

Rewarming

Rapid rewarming at temperatures slightly above normal body temperature may significantly decrease tissue necrosis and reverses tissue crystallization. If there is any possibility of refreezing, the frostbitten part must not be thawed. Ideally the frozen extremity must not be used. Rewarming is best achieved by warm bath emersion. The frozen external extremity is immersed for several minutes in a moving water bath heated to 40–42°C until the distal tip of the part being thawed flushes. If warm water is not available then passive thawing in a warm environment must be done. Dry heat is not recommended because it is more difficult to regulate and increases the chances of accidental burns. Once the frozen part is thawed and return to normal temperature (in about 30 minutes), external heat is discontinued. In the early stage, rewarming by exercise, rubbing, or friction is contraindicated. Application of casts, occlusive dressings, or bandages is avoided. Blisters must be left intact unless signs of infection supervene. Aseptic wound care may reduce the risk of infection. Nonadherent sterile gauge and fluffy dressings should be loosely applied to wounds. Tetanus prophylaxis status must be verified and dealt accordingly.

Medical and Surgical Treatment

Need for amputation have been decreased by the use of intravenous infusion of synthetic prostaglandins and tissue plasminogen activator and intra-arterial thrombolytic within 24 hours of exposure. Clinicians must watch for evidence of compartment syndrome and need for fasciotomy. Eschar formation without evidence of infection may be conservatively treated.

Debridement and amputation may be considered only after it is established that the tissue are necrotic. Prognosis of frostbite depends on the underlying comorbidities, the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae. Neuropathic sequelae include numbness, tingling, pain, hyperhidrosis, and cold sensitivity of the extremities. Nerve conduction abnormalities may persist for many years after a cold injury.

AVALANCHE

The most common cause of death in avalanche burial is asphyxia. A victim who survives an avalanche initially may die from asphyxiation due to hypercapnia and hypoxemia, airway obstruction (constriction of the chest due to snow or other debris and trauma). A rapid decrease in survival occurs during the initial 35-minute asphyxia phase, an air pocket in front of the mouth or nose can slow asphyxiation and prolonging survival. Cooling of a victim of avalanche burial can be rapid, especially if the victim is asphyxiated. The average cooling rate after avalanche burial is about 3°C per hour. The current recommendation is to use standard resuscitation, if burial was 60 minutes or less or core temperature is 30°C or above. If there is return of spontaneous circulation (ROSC), the victim should be evacuated to the closest hospital that is able to manage associated injuries. A victim with vital signs who was buried longer than 60 minutes or with core temperature <30°C should be transferred to the nearest facility capable of providing active rewarming. CPR should be started if the victim is in cardiac arrest and has a patent airway. If the victim does not have a patent airway and is in cardiac arrest, decision to withhold CPR and resuscitation is reasonable. A victim of avalanche burial is most likely to be asphyxiated before becoming hypothermic. The highest serum potassium documented in an avalanche victim who was successfully resuscitated was 6.4 mmol/L. In 2015, the European Resuscitation Council proposed serum potassium of 8 mmol/L as the upper limit for attempting resuscitation of an avalanche victim. Resuscitation should be discontinued if serum potassium is 8 mmol/L or more.

SUMMARY

Hypothermia can be life-threatening. Rescuers should attempt to minimize further heat loss and begin rewarming of hypothermic patients in the field while minimizing after drop and preventing circumrescue collapse. Some patients are cold and dead, but other cold patients who are apparently dead can be resuscitated with full neurologic recovery. Unless there are definite contraindications, rescuers should do their best to resuscitate HT patients, even if they appear to be beyond hope.

240
CHAPTER

Heat Illness

Omar Ghazanfar, Saleh Fares

INTRODUCTION

Heat illness is a common medical emergency in tropical areas, especially the heat stroke is cause of concern, clinically diagnosed as a core temperature >40°C with central nervous system dysfunction or multiorgan dysfunction (core temperature is at which blood perfusion of hypothalamus and vital organ of body like heart brain are maintained, normal core body temperature is 36–37.5°C and rectal temperature being the closest approximation).

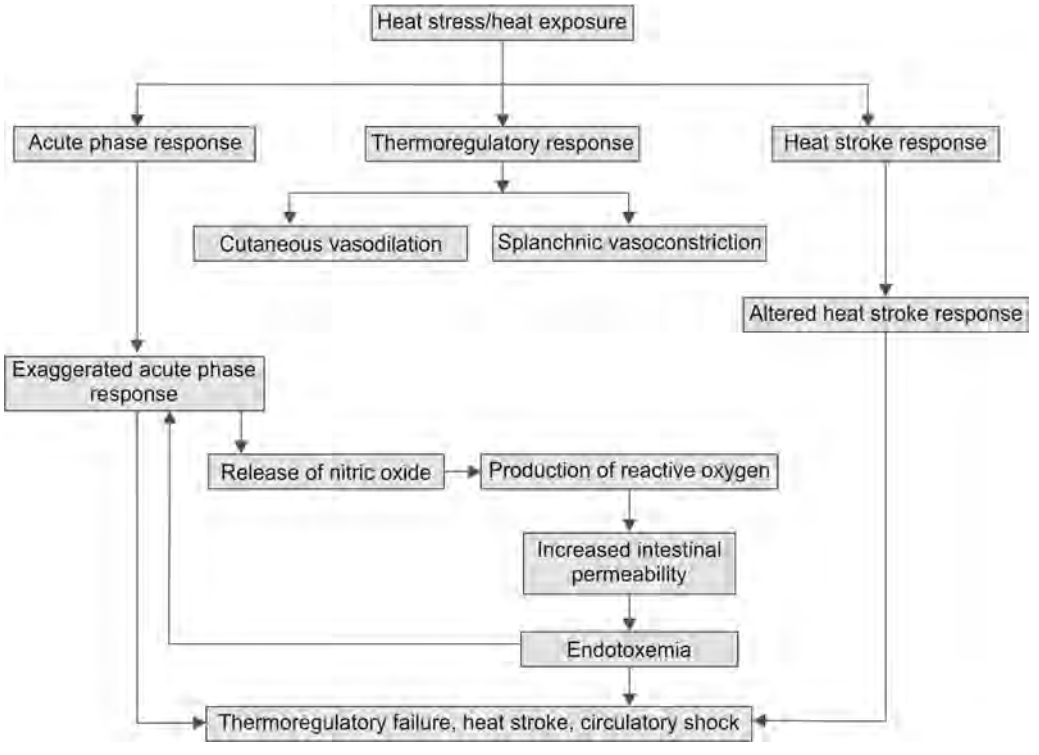
Heat stroke is one of the important treatable causes of multiple organ failure resulting from thermoregulatory failure. Heat stroke problem in tropics is increasing with rise of global warming. In India, Northern and Western India are worst affected due to heat stroke. Exertion-induced heat stroke is reported in military recruits. In spite of advances in the treatment, mortality due to heat stroke remains high. Pathophysiologic changes on exposure to heat are depicted in **Flowchart 1**.

CLASSIFICATION OF HEAT ILLNESS

Heat illness is a spectrum of disorders due to environmental exposure to heat. It ranges from minor conditions such as heat cramps, heat syncope, and heat exhaustion to the more severe condition known as heat stroke. A number of heat illnesses exist across a broad spectrum of presentations (**Table 1**).

HEAT CRAMP

Heat cramps are muscular spasms which result from a loss of salt and water due to excessive exercise. Heat cramps are



FLOWCHART 1: Pathophysiology of heat-related illness.

TABLE 1: Classification of heat illness.

Type	*Characteristic feature*
Heat cramps	Muscular pain which happens after exercise in hot conditions
Heat edema	Cutaneous condition characterized by dependent edema from vasodilatory pooling
Heat rash	Irritation of the skin that results from excessive sweating during hot and humid weather
Heat tetany	A result of short periods of stress in intense heat. Symptoms may include hyperventilation, respiratory problems, numbness or tingling, or muscle spasms
Heat syncope	Dizziness as a result of excess heat
Heat exhaustion	A precursor of a heatstroke; which include heavy sweating, rapid breathing, and a fast, weak pulse
Heat stroke	A core body temperature of >40°C (104°F) due to environmental heat exposure with either a lack or dysfunction of the central and peripheral thermoregulation centre. Symptoms include dry skin, rapid, strong pulse, and dizziness

associated with cramping in the abdomen and calves. This is caused by inadequate intake of fluid and electrolytes. Heavy sweating can also result in heat cramps, especially when the water is replaced without electrolyte replacement.

Heat cramps can be quite painful, but they do not result in permanent damage but can be an early symptom of heat exhaustion and heat stroke. Heat cramps can however indicate a more severe pathology in patients with heart disease or if it lasts for a prolonged period of time. Prevention includes oral rehydration during severe exercise or strenuous work and consumption of eat potassium-rich foods like bananas. After heat cramps occur, the affected patient should avoid strenuous work and exercise for several hours to allow adequate recovery.

HEAT EDEMA

Heat edema is a skin condition characterized by edema in dependant body areas as a result of vasodilatory pooling. Heat causes the blood vessels to dilate, resulting in gravitation of body fluids so body fluid moves into the hands or legs by gravity. The balance of salt in the body is also a risk factor for heat edema. If salt loss is less than normal, the increased salt level draws fluid into the hands and legs. Elderly patients have an increased risk of heat edema, especially if they have other medical conditions that affect their circulation. People visiting hot climates from colder climates may also have an increased risk of heat edema.

HEAT RASH

Heat rash occurs when the skin's sweat glands are blocked, and the sweat produced cannot get to the surface of the skin to evaporate. This causes inflammation that result in a rash. Common symptoms of heat rash include red bumps on the skin and a prickly or itchy feeling to the skin (also known as prickly heat). The rash appears as reddened skin with tiny blisters and is due to inflammation. It often occurs in skin creases or areas of tight clothing where air cannot circulate. Heat rash usually fades when the skin is allowed to cool. Medical treatment is necessary only if the area becomes infected. Heat rash can be prevented by avoiding hot, humid conditions, wearing lose fitting clothes, and using air conditioning or fans to allow air to circulate.

HEAT TETANY

Heat tetany (hyperventilation and heat stress) is usually related to short periods of stress in intense heat environments. Symptoms may include hyperventilation, respiratory problems, numbness or tingling, or muscle spasms. Treatment includes removing the affected person from the heat and slowing the breathing pattern.

HEAT SYNCOPE

Heat syncope occurs in a warm environment when the blood pressure drops due to dilatation of the arterioles in the skin to radiate heat. This condition usually occurs within 5 days of heat acclimatization, before the actual blood volume expands. This subsequently leads to reduction blood to the brain, causing light-headedness and near syncope during sudden postural movements or if the patient remains standing for a prolonged period of time. Individuals who perform strenuous work outside in warm climates are at particular risk.

Symptoms

Symptoms can include faintness, dizziness, headache, increased pulse, restlessness, nausea, vomiting, or brief loss of consciousness.

Diagnosis

The diagnosis of heat syncope is through a history and physical examination. During the physical examination, the healthcare provider should assess the vital signs including postural blood pressure and the pulse. If the patient experiences heat syncope, the patient is usually hypotensive and tachycardic. Excess sweating is also being a key sign. A detailed history is imperative. If the patient develops symptoms during physical activity in high temperatures, then the diagnosis of heat syncope can be made.

Treatment

The basic treatment for heat syncope is similar to other types of syncope. The patient is positioned in a seating or supine position with legs raised. If the patient can tolerate it, oral rehydration with salt or a drink containing electrolytes, can be administered slowly, and the patient is moved to a cooler area preferably under a shade. The affected person should be advised rest; as heat syncope can lead to heat exhaustion and subsequently heat strokes.

Prevention

Physical activity in extremely hot weather should be avoided. In the event of symptoms, the patient should be moved

to a shaded or cooler location. It is also recommended to avoid alcoholic beverages in hot weather as this can lead to dehydration which may exacerbate symptoms. Patients should also be encouraged to increase the intake of oral fluids during physical activity.

HEAT EXHAUSTION

Heat exhaustion is often a precursor of heat strokes if the patient is not treated appropriately and in a timely manner. Etiology and risk factors include hot, sunny, humid weather along with physical exertion in extremes of heat. Impaired thermoregulation in extremes of age results in geriatric and pediatric patients suffering from severe heat illness even at rest, if the weather outside is hot and humid with a lack of ventilation. Drugs including diuretics, antihistamines, and beta-blockers and agents of misuse such as alcohol, ecstasy, and amphetamines can also increase the incidence of heat exhaustion. During physical exertion, risk factors for heat exhaustion include wearing dark, padded, or insulated clothing; hats; and/or helmets in some professions, having a higher percentage of body fat, and lack of fluid intake leading to dehydration as well as pyrexia.

Symptoms

Symptoms include dizziness, nausea, headache, increased thirst, raised core body temperature, increased sweating, and reduced urine output. Heat exhaustion should be differentiated from heat stroke (**Table 2**).

Treatment

Basic management includes moving the person to a cool place with removal of extra layers of clothes. Passive cooling by fanning wet towels and increase intake of oral fluids, if the patient is conscious. Specific management includes following the usual Airway, Breathing and Circulation (ABC) approach. Supplemental oxygen may be required and if the patient is confused with impaired level of consciousness and/or vomiting, intravenous fluids and electrolyte replacement is needed.

TABLE 2: Differentiating heat exhaustion from heat stroke.

Heat exhaustion	• Heavy sweating • Heavy thirst • Rapid breathing • Headache blurred vision • Confusion • Dizziness • Cramps
Heat stroke	• No sweating • Red flushed hot dry skin • Symptoms of heat exhaustion are more severe • Difficult breathing • Confusion altered behavior • Convulsion collapse

HEAT STROKE

Heat stroke is a type of severe heat illness that results in a core body temperature of >40.0°C and associated with confusion. Other symptoms include red, dry or damp skin, headache, and dizziness which can be sudden or gradual. Complications can include seizures, rhabdomyolysis, and renal impairment.

Heat stroke results from extreme high environmental temperatures or severe physical exertion. There are certain *risk factors* (**Box 1**) including heat waves, humidity, and *medications* (**Box 2**) which include diuretics, beta-blockers, and alcohol as

BOX 1: Risk factors for heat stroke.

- Age >65 or <15
- Cognitive impairment
- Heart or pulmonary disease
- Poor access to ventilation
- Psychiatric illness
- Obesity
- Physical disability
- Poor fitness level
- Sickle cell trait
- Excess physical activity in high temperature
- Urban residence, especially on high floors
- Heat wave
- Drugs
- Current febrile illness
- Skin disease
- Lack of acclimatization
- Previous heat stroke
- Increased heat index
- Alcohol consumption
- Lack of sleep, food, and water

BOX 2: Medications and substances that contribute to heat-related illness.

- Alcohol
- Alpha-adrenergic agonists
- Amphetamines
- Anticholinergics
- Antihistamines
- Benzodiazepines
- Beta-blockers
- Calcium channel blockers
- Cocaine
- Diuretics
- Ephedra supplements
- Laxatives
- Neuroleptics
- Phenothiazines
- Stimulants

well as cardiac disease and skin pathology. Extremes of age and individuals with long-term chronic illness not associated with physical exertion typically occur in extremes of age or with chronic health problems. Heat stroke is a type of hyperthermia and is a pathological increase in the body's core temperature set point. Drinking sufficient fluids and avoiding excessive heat can be an effective preventative measure. Treatment includes rapid physical cooling of the body and supportive measures. Spraying the patient with water and using a fan, or placing the patient in an ice bath, or giving cooled intravenous fluids are some of the measures which can be taken. Adding ice packs is not routinely recommended. Heat stroke results in >600 deaths a year in the United States. Rates have increased in the last decade. The risk of death is over 5% in those with exercise-induced heat stroke and >65% in those with nonexercise-induced cases. Heat stroke can be classified as:

- Classical heat stroke
- Exertional heat stroke

Classical Heat Stroke

It is usually affected older age group with limited mobility and/or chronic diseases, and individual vulnerable to excessive environmental temperature and humidity. Laboratory feature like respiratory alkalosis is common.

Exertional Heat Stroke

It is usually seen in young healthy individual who overexert in the heat and humidity. Respiratory alkalosis with lactic acid, rhabdomyolysis, renal failure, disseminated intravascular coagulation (DIC), and hyperuricemia are frequently seen.

Symptoms

Heat stroke presents with a hyperthermia of >40.0°C in conjunction with disorientation and anhidrosis. Early signs include dizziness, mental confusion, headaches, and weakness. In exertional heat stroke, the affected person may sweat excessively. Pediatric patients may have seizures. Eventually there is impairment of consciousness, multiorgan failure, and death.

Etiology

Heat stroke occurs when the thermoregulation system is overwhelmed by a combination of excessive metabolic production of heat excessive environmental heat and insufficient or impaired heat loss. Alcohol, stimulants, medications as well as extremes of age can result in nonexertional heat strokes. Exertional heat stroke can occur in young individuals without existing health problems or medications and the spectrum of patients include athletes, outdoor workers, military personnel on outdoor maneuvers as well as emergency medical services (EMS) first responders wearing heavy personal protective equipment (PPE). In hot and humid environments, the humidity tends to reduce the degree to which the body can self-regulate the temperature by sweating and evaporation. Excessive body temperature can disrupt enzymes regulating biochemical reactions that are essential for cellular respiration and organ functions.

Young children, elderly adults, or disabled individuals left alone in a vehicle are at high risk of heat developing a stroke. In child deaths in hot cars, approximately 50% happened because parents forgot that the child was in the car, 18% happened after parents intentionally left the child in the car without understanding how hot it could get, and 30% happened after the child climbed into the car to play. This can have medical as well as legal consequences.

Prevention

The risk of heat stroke can be reduced by observing precautions to avoid overheating and dehydration. Light and loose-fitting clothes will allow perspiration to evaporate and cool the body. Wide-brimmed hats in light colors help to prevent the sun from warming the head and neck. Vents on a hat will help cool the head. Strenuous exercise should be avoided during daylight hours in hot weather. People working in confined spaces (such as automobiles) without air conditioning or ventilation, advised to maintain adequate hydration to prevent dehydration.

Treatment

Maintain ABC and cardiac monitoring. Important recommended investigations are summarized in **Box 3**. Treatment of heat stroke involves rapid mechanical cooling along with resuscitation measures. The body temperature must be lowered quickly. The patient should be moved to a cool area which is either indoor or in a shade and clothing may need to be removed to promote passive clothing. Active cooling methods include immersion in cold water, or a hyperthermia vest can be applied. Cold compresses to the torso, head, neck, and groin will help in bringing the body core temperature down. A fan or dehumidifying air conditioning unit may be used to aid in evaporation of the water (**Fig. 1**).

Immersion should be avoided for an unconscious person, but if there is no alternative, the patients' head must be held above water. Dantrolene, a direct-acting paralytic which abolishes shuddering and is effective in many other forms of hyperthermia has no individual or additive effects to cooling in the context of heat stroke, showing a lack of endogenous thermogenic response to cold water immersion. Aggressive ice-water immersion is the gold standard for life-threatening heat stroke.

BOX 3: Investigations in heat-related illness.

- Monitor core body temperature regularly
- CBC
- LFTs
- U&E
- Glucose
- Urate—may be a predictor of acute kidney injury
- Creatine kinase—may be a predictor of rhabdomyolysis
- Coagulation studies
- Arterial blood gases
- Urinalysis—may show myoglobinuria and impending acute kidney injury
- ECG
- CXR—to check for aspiration/pulmonary edema

(CBC: complete blood count; CXR: chest X-ray; ECG: electrocardiogram; LFTs: liver function tests; U&E: urea and electrolytes)

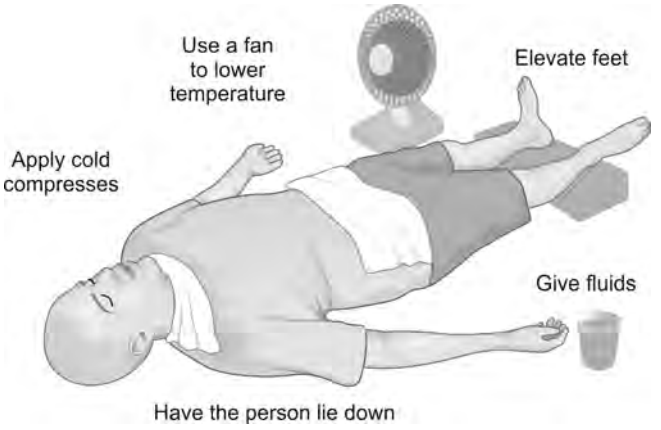


FIG. 1: Supportive measures for managing heat stroke.

Adequate hydration is essential adjunct to cool the temperature. In mild cases of dehydration, hydration can be achieved by drinking water or isotonic sport drinks. In exercise- or heat-induced dehydration, an imbalance of electrolytes can occur and is exacerbated by overconsumption of water. Hyponatremia can be corrected by intake of hypertonic fluids. Absorption is rapid and complete in most people, but in the event of confusion, impaired conscious level or if the patient is unable to tolerate oral fluid, then an intravenous rehydration and electrolyte replacement may be required. The person's condition should be reassessed at regular intervals including the vital signs to ensure stability.

Prognosis

It was believed that heat strokes rarely lead to permanent deficits and that the recovery is almost complete. However, research has showed that patients with heat stroke severe enough to require intensive care can leave to high percentage of morbidity and mortality. Some patients can have permanent loss of independent function or severe functional impairment at discharge which was persistent even 12 months after discharge from the healthcare facility.

SUMMARY

Heat illness is a wide spectrum of different symptomatology which can range of heat cramps to heat stroke with a multitude of pathologies within the spectrum. Extreme heat can affect any individual; however, the elderly and children are more susceptible to heat stress along with people with preexisting medical problems. Heat stress generally occurs when the body's thermoregulatory systems are unable to cope with extremes of temperatures and can lead to a wide spectrum of heat-related illnesses ranging from the simple heat cramps to the life-threatening heat stroke. Treatment revolves from instigating basic measures to remove the individual from the source as well as more advanced treatment strategies which include passive or active cooling as well as intravenous fluid and electrolyte replacement. The emphasis should however be on prevention strategies, especially in extremes of ages where heat stress can be life-threatening and result in significant morbidity and mortality.

241
CHAPTER

Decompression Illness

Goma Bajaj, Devendra Richhariya

INTRODUCTION

Diving is a popular outdoor and pastime activity with numerous scientific benefits, though underwater environment is unforgiving and diving can be done safely. To avoid any problem during diving acquire sufficient medical or physical fitness and sound knowledge about use of equipment at high-pressure environment. Decompression illness (DCI) is a manifestation due to arterial gas embolism (AGE). AGE develops due to pulmonary barotrauma, alveolar wall damage, and gas enters into the systemic arterial circulation. Decompression sickness (DCS) develops due to large amount of gas release from tissue during or while coming to surface and less time for equilibration (decompression) of DCI incidence rates in the recreational community range from 2.0 to 4.0 per 10,000 person-dives. The DCS incidence rate in commercial decompression diving has been reported to be as high as 35.3 per 10,000 person-dives.

DIVING PHYSICS

Ambient pressure helps in dissolving inert gas within body tissues which is normally exist in equilibrium in a saturated state. When any pressure differences (gradients) develop, molecules move from higher to lower concentration until equilibrium is reestablished. The pressure of the diving environment is much greater than the pressure of the surface environment. The lungs when exposed to increased pressure underwater, the gas in the lungs is compressed and creates an inflow gradient from concentrated lung gas to the bloodstream and, subsequently, from the bloodstream into tissues as they are perfused. Lungs plays an important role in gas uptake and elimination and finally in decompression stress.

DEVELOPING DECOMPRESSION SICKNESS

Although DCS is commonly thought of as a bubble disease, bubbles are probably only the gateway to a complex array of consequences. Bubbles can develop within the tissues or reach to different and initiate biochemical cascades to produce secondary insults and effects. Vascular obstruction or interactions may stimulate platelet aggregation, leukocytes activation and aggregation, and fibrin deposition. Intravascular air may cause capillary endothelium damage, increased in endothelial permeability, and tissue edema exacerbating the ischemia process. Other possible contributing process is increased in release of cytokines complement activation and inflammatory cascade could play an important role in the pathophysiology of DCI. The in-activation variability of this inflammatory cascade might explain the differences between individuals in susceptibility to DCS. The inflammatory and coagulation cascades might also explain the failure of recompression treatment in some cases because, once activated, the resolution of bubbles will not immediately stop the response. A rapid ascent with full lungs and an obstructed airway from this very shallow depth could result in pulmonary barotrauma. Tissue rupture will allow gas from the alveolar space to enter the pleural space (pneumothorax), the pulmonary interstitium, the mediastinum (pneumomediastinum), and/or the pulmonary capillaries. Bubbles entering the pulmonary capillaries can be transported into the systemic arterial circulation and may reach critical tissues, such as the brain or the spinal cord, to produce serious symptoms. The symptoms of AGE can be very similar to those of DCS, sometimes making them difficult to separate.

SIGNS AND SYMPTOMS

Clinical manifestations of DCS categorized as type 1 and type 2. Type 1 DCS manifestations are mild and musculoskeletal pain and mild cutaneous symptoms and type 2 clinical manifestations are more serious. Itching and mild rashes (clear, mottled or marbled, and sometimes raised discoloration cutis marmorata) are common skin manifestations in type 1 category. Musculoskeletal manifestations of type 1 DCS are articular or periarticular pain and shoulders, elbows, wrists, hips, knees, and ankles joints are commonly involved. The joint pain (present at rest) may range from mild to severe, usually has a gradual onset and presents as a deep dull ache (**Table 1**).

Type 2 symptoms are divided into three categories: neurologic, inner ear, and cardiopulmonary. Neurologic symptoms include numbness; paresthesia or tingling; muscle

TABLE 1: Clinical manifestations of the decompression sickness.	
Skin	Itching, nonspecific skin rash, urticarial rash, and well-organized mottling (cutis marmorata)
Lymphatics	Localized pain in the region of lymph nodes, localized skin, and soft tissue swelling (lymphedema)
Musculoskeletal	Articular or periarticular pain, muscular pain, and usually no joint swelling and no redness
Respiratory	Dyspnea, cough, respiratory distress, retrosternal pain worsened on inspiration, tachypnea, tachycardia, hypotension, frothy bloody sputum, and low oxygen saturation
Central nervous system	Headache, unexplained fatigue, malaise, dizziness, impaired cognitive processes, paresthesia, limb weakness, speech difficulty, visual loss, ataxia, nausea, vomiting, convulsions, altered state of consciousness, confusion, visual field deficit, unusual distribution of sensory deficits, motor deficits, coordination deficit, gait and walking disturbance, ataxia, and positive Romberg sign
Spinal cord	Back pain, girdling abdominal pain, numbness, paresthesia, limb weakness, urinary or fecal dysfunction (with urinary issues being more common), motor and/or sensory deficits, anal sphincter weakness, urinary retention, loss of bulbocavernosus reflex, and loss of deep tendon reflexes
Peripheral nervous system	Numbness or paresthesia in a peripheral nerve distribution and patchy sensory deficits
Inner ear	Deafness, vertigo, nausea, vomiting, ataxia, tinnitus, acute sensorineural hearing loss, and nystagmus
High likelihood of decompression sickness if symptoms appear >10 min to 6 h duration (low likelihood if >12 h)	

weakness; impaired gait, physical coordination, or bladder control; paralysis; or change in mental status. Other neurologic features are headache, light-headedness, unexplained fatigue, malaise, nausea and/or vomiting, or anorexia. Inner ear symptoms include tinnitus, hearing loss, vertigo or dizziness, nausea, vomiting, and impaired balance. Cardiopulmonary symptoms occur when large bubble obstruct the large area of pulmonary vascular bed and may presents as the choking, dry cough sometime with pink frothy sputum, retrosternal pain, and dyspnea. Differentiate immersion pulmonary edema from cardiopulmonary DCS. Development of type 2 symptoms can be insidious or quick. Features such as walking difficulty, urinating problem, hearing problem, or vision problem can also occur. The following list ranks the initial manifestations of DCS, with frequency estimates for each: pain, particularly near the joints (68%), numbness or paresthesia (63%), constitutional symptoms (41%), dizziness or vertigo (19%), motor weakness (19%), cutaneous changes (10%), impaired mental status (8%), impaired coordination (8%), muscle discomfort (7%), pulmonary symptoms (6%), bladder or bowel dysfunction (3%), auditory symptoms (2%), impaired consciousness (2%), lymphatic involvement (2%), and compromised cardiovascular function (<1%).

Severe neurologic DCS symptoms usually appear within 10 minutes of surfacing and in 90% of cases symptoms will be present within the first 3 hours. In some cases, it can take up to 24 hours for symptoms to be noticed by the diver.

MEDICAL ASSESSMENT OF THE INJURED DIVER

The management of suspected DCS starts with history and physical examination. In addition to the usual medical questionnaire, the emergency physician should seek the following information: Time of onset and evolution of symptoms and signs: Onset of symptoms <10 minutes after surfacing could indicate AGE while >10 minutes after surfacing is more likely associated with DCS.

Profiles of the Recent Dives

Depth-time exposure, ascent rate, ascent stops (obligatory decompression stops or nonobligatory safety stops), and patterns of repetitive dives should be noted. Greater depth and duration imply a larger inert gas burden, but using maximum depth alone to assess severity can be misleading given the common use of multilevel dive profiles. The use of oxygen-enriched mixtures (nitrox) and helium-oxygen and helium-oxygen-nitrogen mixtures (trimix) is increasingly common by divers. Decompression stress is reduced by using nitrox.

Thermal Stress

Decompression stress also increases with being warm during the descent and/or bottom phase of a dive. Being cold during the ascent and/or stop phase inhibits inert gas elimination, increasing the decompression stress.

Exercise Stress

Decompression stress increases subsequently with exercise during the descent and/or bottom phase of a dive as increase in inert gas uptake. Light exercise during the ascent and/or stop phase promotes inert gas elimination, reducing the decompression stress. Vigorous exercise during the ascent and/or stop phase can promote bubble formation and increase risk. After-dive exercise, particularly with high joint forces, can promote bubble formation and increase risk.

Altitude Exposure and Diving

Flying to a destination near sea level before diving creates no risk (outside the possibility of mild dehydration or impairment due to long periods of relative immobility). Flying soon after diving increases decompression stress because the pressure in an aircraft cabin is below ground-level atmospheric pressure.

State of Hydration

Dehydration is often considered as a risk factor and can elevate the decompression stress of a given exposure.

Contributing Factors

Assessment of physical and medical fitness (present or chronic) including history of DCS and medication use should be done. The physical evaluation should focus on:

- *Vital signs*: Any changes in vital signs should be evaluated rapidly and managed urgently. Vital signs should include rectal temperature to detect hypothermia or heat exhaustion. Causes of shock may be cardiopulmonary DCS, tension pneumothorax, hypovolemia due to physical trauma, or from a neurogenic shock due to spinal cord DCS. Blood glucose level should be measured to rule out hypoglycemia in any patient presenting with altered state of consciousness or neurologic symptoms.
- *Cardiac and lung auscultation*: Evaluate for breath sounds on each side, subcutaneous emphysema, displaced trachea, and Hamman's sign (potentially indicating pneumothorax or mediastinal emphysema from a pulmonary barotrauma).
- *Ear examination*: Evaluate for signs of middle ear barotrauma that could be associated with inner ear damage.
- *Neurologic examination*: Evaluate mental status, cognitive function, gait and walking, cranial nerves, sensory function, limbs strength, cerebellar function, and reflexes. Anal sphincter tone and bulbocavernosus reflex are essential to verify in patients with suspected spinal cord DCS and possible spinal shock. Neurologic examination can show very unusual distribution of deficits because bubbles can cause vascular occlusions at many different locations in the nervous system and can be confusing for the physician so unusual neurologic complaints or findings should not be dismissed as imaginary.
- *Skin examination*: Any rash or swelling should be noted.
- *Joint examination*: Joint examination is often inconclusive; pain may be the only presentation in DCS because there are usually no signs of joint inflammation and joint movement rarely alters the pain.
- *Abdominal examination*: Evaluate for bladder distension that can be present with spinal cord DCS. If present, urinary catheterization will be mandatory.

DIAGNOSTIC WORKUP

For establishing the diagnosis of DCS there are no specific diagnostic investigations available. Useful laboratory investigations are hemoglobin-hematocrit, (severe DCS associated with hemoconcentration due to increased vascular permeability mediated by endothelial damage and kinin release). In the evaluation of the injured divers, chest radiographs are essential to exclude pneumothorax and pneumomediastinum. A pneumothorax should be treated first before recompression in a hyperbaric chamber. It may also be crucial to recognize and treat a pneumothorax before any medical evacuation to the hyperbaric center. Patient with tension pneumothorax should be resolved before air transportation of the DCS patient. Secondarily, chest radiographs may be helpful in differentiating drowning and immersion pulmonary edema. Computed tomography (CT) and magnetic resonance imaging (MRI) are useful to rule out cerebral and spinal cord lesions in patients suffering from neurologic DCS. MRI may also be helpful in predicting clinical outcome in divers with spinal cord DCS. CT scanning may be helpful in excluding other causes of neurologic symptoms, such as subarachnoid hemorrhage or cerebrovascular accident. Emergency physician must understand that in clear cut cases of neurologic DCS, first priority is recompression therapy and CT/MRI is not the priority. Limb radiographs may show evidence of gas in the soft tissue and periarticular spaces, but the absence of such finding does not exclude DCS. Limb radiographs are not recommended as part of the routine evaluation for DCS. It has been demonstrated in the research that coagulation activation can be present in DCI and relationship has been found between the plasma D-dimers level and the presence of sequelae in neurologic DCS.

DIFFERENTIAL DIAGNOSIS OF DECOMPRESSION ILLNESS

Decompression illness should be differentiated from the other conditions with similar symptoms including inner ear barotrauma; middle ear or maxillary sinus barotrauma; contaminated breathing gas; oxygen toxicity; musculoskeletal strains or trauma sustained before, during, or after a dive; seafood toxin ingestion; immersion pulmonary edema; water aspiration; and coincidental neurologic disorders, such as stroke. Hypoglycemia, thermal stress, and age-related conditions should also be considered. Medical or event history can provide important insights.

TREATING DECOMPRESSION ILLNESS

There are several steps in DCI management: on-the-scene evaluation and first aid, transport, and definitive medical evaluation and treatment. Providing high partial pressure oxygen is the primary first aid measure for DCI. Inert gases from the lung will be eliminated by providing high oxygen concentration to the patient. Ischemic insults produced by bubble blockages can also be minimized by high oxygen partial pressure in the bloodstream. Sustained oxygen delivery can reduce or even eliminate symptoms. Various oxygen delivery systems are available at diving site such as continuous flow oxygen systems and nonrebreather or pocket masks; however, such equipment delivers modest oxygen fractions. With the help of demand valve oxygen therapy (DVOT), higher fraction of oxygen can be achieved for spontaneously breathing patient. Oxygen rebreather systems can also provide the highest fractions with minimal gas use. Chemical oxygen generating systems may be the only option available in some remote locations, but these systems provide only limited flow rates and volumes. Even if a diver's symptoms improve or disappear with the administration of oxygen, detail medical evaluation is advised because subtle issues can be missed or signs and symptoms can return once oxygen delivery is stopped.

HYPERBARIC OXYGEN THERAPY

The definitive treatment of DCI is hyperbaric oxygen therapy (HBOT), the delivery of oxygen at a partial pressure substantially higher than that achievable at normal atmospheric pressure. Recompression therapy in a hyperbaric chamber reduces the volume of bubbles. Both bubbles and dissolved gas are eliminated by HBOT. HBOT improves delivery of oxygen to ischemic tissues, blood vessel permeability and tissue edema is

reduced. The initial pressurization is to 2.8 ATA, equivalent to the pressure found at 18 m (60 ft) of seawater. Patients breathe pure oxygen, with scheduled air breathing breaks to reduce the risk of central nervous system oxygen toxicity. The usual duration of the treatment is just under 5 hours, but duration can be extended pressures depending on patient's response. HBOT can be conducted in monoplace chambers (can accommodate only one patient) or multiplace chambers (can accommodate more than one patient).

Treatment Efficacy

In view of limited definitive data and research, rapid HBOT is the best available option for achieving the good prognosis. Delay in starting the treatment associated with incomplete resolution of symptoms. But researchers are not able to establish a maximum time after which recompression is ineffective. Many anecdotal reports describe clinical improvement in DCS cases treated many days after the onset, even with neurologic involvement. So, HBOT therapy can be initiated even several days after the first symptoms. The course of HBOT therapy and duration will vary according to the particulars of each case. Full resolution of DCS symptoms can often be achieved with one or sometimes multiple HBOT treatments. The normal clinical approach is to continue treatments until no further improvement is seen in the patient's symptoms. Sometimes residual symptoms resolve slowly, over a period of times after the HBOT therapy is ended. Full resolution of symptoms can sometimes take months.

ADJUNCTIVE THERAPIES

Fluid Administration

Fluid resuscitation is recommended for the treatment of divers with DCS. Isotonic fluids are preferred choice over hypotonic fluids to prevent an osmolar gradient that may contribute to tissue edema and to prevent electrolyte imbalance. The goal is to maintain a good urinary output (1–2 mL/kg/h).

Anticoagulants and Antiplatelet

Inert gas bubbles cause platelet accumulation, adherence, and thrombus formation so antiplatelet and anticoagulants are included in the therapy, but fail to show any benefit. Aspirin is commonly administered to divers suffering from DCI but has no benefits. Heparin has no beneficial therapeutic effect and may also pose a significant risk of hemorrhage in both spinal cord DCS and inner ear DCS. Administration of subcutaneous low-molecular-weight heparin for thromboembolic prophylaxis is recommended for bedridden patients.

Corticosteroids

Corticosteroids were the important components for the treatment of neurologic DCS. According to various studies, use of high-dose corticosteroids in acute traumatic spinal cord injuries may have limited benefit and can cause invasive infections and avascular necrosis. Currently, the efficacy of corticosteroids in DCI treatment remains unproven.

Nonsteroidal Anti-inflammatory Drugs

Studies do not show any benefits of adding nonsteroidal anti-inflammatory drug (NSAID), tenoxicam, in the treatment of DCS. NSAIDs are not recommended in the initial first-line treatment of DCS because they can confound the clinical evaluation by masking the pain.

ALTERNATIVE TREATMENT TECHNIQUE: IN-WATER RECOMPRESSION

In the remote locations where HBOT and recompression chambers are not available or no facility available for quick transfer of the patient, in-water recompression may be an alternative to chamber recompression. This technique involves bringing the diver underwater again, to make gas bubbles back into solution, elimination of the excess gas to reduce symptoms. The concept of in-water recompression looks simple, but it is practical only with great amount of planning, manpower support, equipment, appropriate water conditions, and suitable patient status.

Patient's consciousness, oxygen toxicity, gas supply, and even thermal stress poses critical challenges during this procedure. An unsuccessful in-water recompression may deteriorate the condition of the patient. The medical and research communities do not have consensus over utility of in-water recompression. As a general rule, a diver who develops symptoms of DCS should be removed from the water and receive oxygen first aid on the surface without delay and transfer to advanced medical center for definitive medical care.

SUMMARY

Decompression illness though rare but is a major concern for divers as well as for emergency physician because of its potential severity and risk of sequelae. Signs and symptoms of DCS depend on multisystem involvement. They frequently involve much more than the classic description of joint pain, with neurologic symptoms increasingly recognized. Neurologic examination findings can be confusing. History and physical examination are important for evaluation. Symptoms will not develop during the bottom phase of a dive, before decompression. Symptoms of AGE develop within 10 minutes of surfacing. Symptoms of DCS normally appear within 6 hours after surfacing, but they may not become apparent for >24 hours. DCS should be differentiated from various other conditions. High-concentration oxygen is the best first aid for both DCS and AGE. HBOT is the normal definitive medical treatment. The search for adjunctive therapies continues but none have been convincingly supported. Early consultation with diving medicine specialists is recommended.

242 CHAPTER

Drowning

Pratika Agarwal, Devendra Richhariya

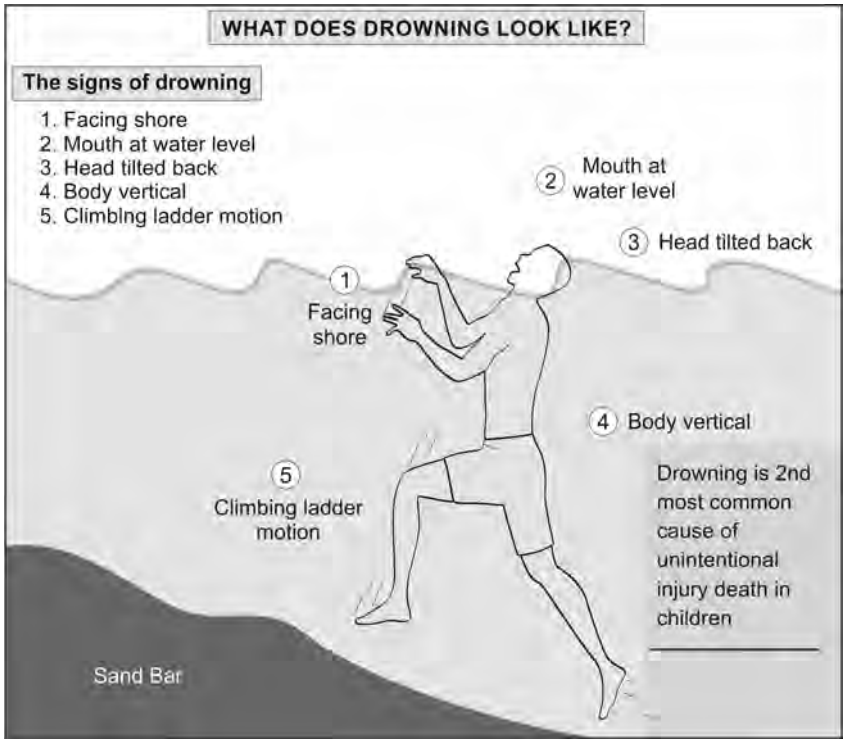
INTRODUCTION

Drowning is a leading cause of accidental death around the world, especially in children (among 5–14 years of boys) and young adults. World Health Organization (WHO) estimates about 0.7% (>500,000) of all death worldwide are due to drowning. There are an estimated 8 million nonfatal drownings worldwide each year, many of which may lead to severe morbidity.

More important, it is a disease that can be prevented through improved public education and treated appropriately through a simple understanding of the underlying pathophysiology. The primary cause of systemic injury in drowning patients is hypoxemia, and its correction should be the focus of prehospital and ED resuscitation and treatment. Once the condition is stabilized, the disposition of a patient can be determined by physical examination findings and response to treatment, with patients displaying mild symptoms are able to be safely discharged after a short period of observation. Overview of the drowning is shown in **Figure 1**.

DEFINITION AND TERMINOLOGY

According to WHO, drowning is defined by "drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid." Immersion is when upper



WHAT DOES DROWNING LOOK LIKE?
The signs of drowning
1. Facing shore
2. Mouth at water level
3. Head tilted back

5. Climbing ladder motion
2 Mouth at water level
3 Head tilted back
1 Facing shore
4 Body vertical
5 Climbing ladder motion
Drowning is 2nd most common cause of unintentional injury death in children
Sand Bar

FIG. 1: *Overview of drowning*: Drowning person not able to clear his/her airway and water enter the mouth. Some amount of water swallowed and spat out. Person cannot hold the breath >1 minutes and water is aspirated into the lungs if the person is not rescued, water aspiration continues, hypoxia leads to apnea and loss of consciousness and finally asystole.

airway above water (water splash over the face) and exhibits cardiorespiratory response to skin and deep body temperature. Submersion is when upper airway under the water. Submersion is associated with upper airway reflexes, water aspiration, swallowing emesis, and electrolyte disorders. Extent of cardiac pulmonary and neurological injury determines the submersion outcome. If no evidence of respiratory impairment during immersion and submersion is not considered as a drowning and considered as water rescue. If person is rescued any time, interruption of drowning process is nonfatal drowning. While fatal drowning is when death occurs at any time as a result of drowning. The terms like "near drowning", "dry/wet drowning", "active/passive drowning", and "secondary drowning" should not be used now.

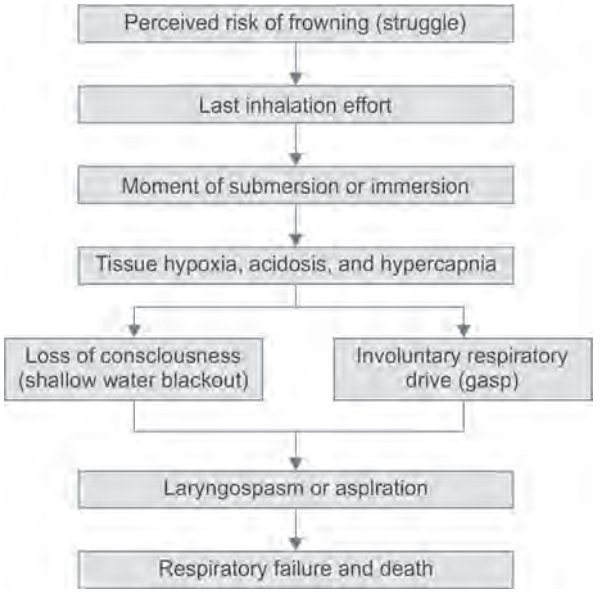
RISK FACTORS FOR DROWNING

Main risk factors for drowning are male with age <14 years, alcohol and other substance abuse, along with risky behavior, and patient with epilepsy cardiac problems (arrhythmias) are also at high risk. Age-wise distribution of risk factors is shown in **Table 1**.

PATHOPHYSIOLOGY AND STAGING OF DROWNING

In the first event, in the sequence of drowning person who is not able to clear the airway, water starts entering the oral cavity and water spats out or is swallowed. Person starts holding the breath but not able to hold it more than a minutes and water aspirated to airway. Reflex response occurs as coughing or laryngospasm (onset of brain hypoxia). At this point, if person is not rescued then aspiration of water and hypoxia leads to apnea, loss of consciousness, cardiac dysrhythmias and asystole. Whole sequence of events from immersion, submersion, aspiration of water, laryngospasm, hypoxia, apnea, loss of consciousness, tachycardia, bradycardia, pulseless electrical activity (PEA), and finally asystole completes in few minutes. Process can take hours in conditions such as hypothermia and ice water drowning. Pathophysiology and staging of drowning are summarized in **Flowchart 1**.

If person is rescued alive then clinical presentation depends on how much water is aspirated to the lung. Aspirated water causes dysfunction of surfactant which is present in alveoli. A very delicate alveolar-capillary membrane is also disrupted due to osmotic gradient differences, increase in permeability of the membrane, and shift of fluid, plasma, and electrolytes, this leads to blood-stained pulmonary edema and finally decreases in exchange of oxygen and carbon dioxide. Finally in decreased lung compliance, larger areas in the lung are evolved where ventilation perfusion ratio is either very low or zero, atelectasis bronchospasm also persists. Though the hypothermia (drowning in cold water) provides protective mechanism by delaying cellular anoxia, adenosine triphosphate (ATP) depletion decreases oxygen consumption by the brain (5% with each reduction of 1°C between 36°C and 20°C).



Perceived risk of frowning (struggle)
Last inhalation effort
Moment of submersion or immersion
Tissue hypoxia, acidosis, and hypercapnia
Loss of consciousness (shallow water blackout)
Involuntary respiratory drive (gasp)
Laryngospasm or aspiration
Respiratory failure and death

FLOWCHART 1: Pathophysiology and stages of drowning.

TABLE 1: Risk factors for drowning as per age group.

Infants	*Children and adolescents*	*Adults*	*All ages*

RESCUE FROM WATER AND RESUSCITATION IN DROWNING VICTIM

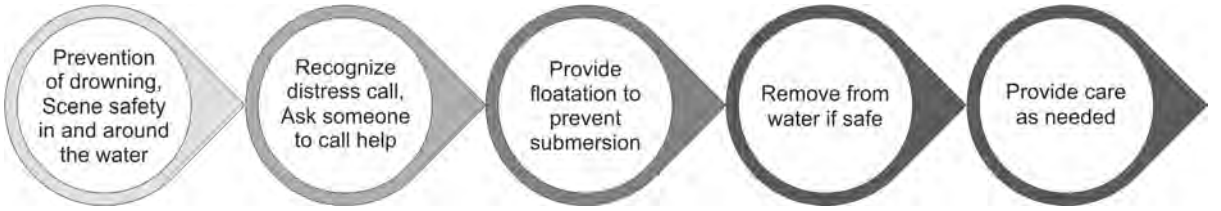
Prehospital Care of Drowning

Drowning Chain of Survival

There are five critical links, which are described in drowning chain of survival in **Figure 2** in which first link is measures for prevention of drowning and make sure scene safety in and around the water, second link is identification of distress person from the water and also ask someone to call for more help, third link is throw the floatation toward distress person, fourth link is remove the victim if it is safe to do, and provide medical help as per requirement in fifth link.

Water Rescue and in Water Resuscitation

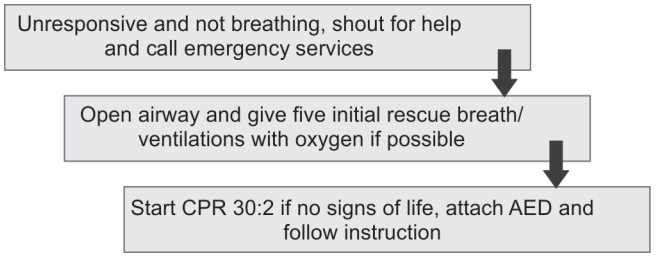
Bystander and Trained Rescuer response: Bystander plays important role in rescue and resuscitation. But death of the bystander is reported if they try to attempt rescue in fast running water. So, it is advisable to bystander to avoid entering the water, or help victim with throwing rope or rescue aid and floatation device toward them. Two bystander rescuers can enter the water instead of one and never jump with head first into the water because of risk of spinal injury. *Trained rescuers* are professional and work with team and special



Prevention of drowning, Scene safety in and around the water
Recognize distress call, Ask someone to call help
Provide floatation to prevent submersion
Remove from water if safe
Provide care as needed

FIG. 2: Drowning chain of survival.

equipment. If rescue takes <10 minute of time, favorable outcome is expected. >25 minutes of submersion is associated with poor outcome. *In water resuscitation* can be given by the trained rescuer/surf lifeguard as they take water breathing apparatus inside and start giving the ventilation alone to the victim, attempting chest compression is not helpful. Further action can be decided on the basis of other situation such as distance to land and availability of rescue boat. Victim should be removed promptly from water, chances of spinal injury are very rare in drowning victim unless there is history of shallow water diving and use of water slide. Rescuer should try to keep the victim in vertical position with airway open to avoid vomiting and aspiration.



Unresponsive and not breathing, shout for help and call emergency services
Open airway and give five initial rescue breath/ ventilations with oxygen if possible
Start CPR 30:2 if no signs of life, attach AED and follow instruction

(AED: automated external defibrillator; CPR: cardiopulmonary resuscitation)

FLOWCHART 2: Cardiopulmonary resuscitation in drowning.

Initial Resuscitation on Land

Once the drowned person is taken to the land, he/she should be in supine position and standard protocol should be followed like check for responsiveness and respiration. Person should be kept in recovery position (lateral decubitus), if unconscious but breathing. Person needs only ventilation if gasping pattern or apnea and heart is still beating. Cardiac arrest in drowning is due to hypoxia so follow traditional cardiopulmonary resuscitation (CPR) airway, breathing, and circulation (ABC) sequence rather than circulation-breathing-airway (CAB) sequence. Initially, five rescue breaths are given followed by 30 chest compressions, and continue till signs of life reappear or rescuer becomes exhausted. European Resuscitation council recommends five initial rescue breaths instead of two initial rescue breaths. Drowning cardiopulmonary resuscitation algorithm is shown in **Flowchart 2**. During the resuscitation in drowning person, lots of foam (admixing moving air and water) will keep coming, do not try to remove until it prevents ventilation completely. In this situation, turn the victim on their side and direct suctioning to remove regurgitated material. Regurgitation of gastric content and aspiration is most frequent complications during CPR in drowning which further cases difficulty in initiation of ventilation. Dry the victim chest, attach the pads and turn on the automated external defibrillator (AED), and follow the instructions of AED.

Advanced Prehospital Care

After initiating the basic life support to drowning person, start advanced life support as soon as possible as drowning presents with wide variety of clinical symptoms. Person with drowning and pulmonary damage should be given oxygen by mask at the rate of 15 L/min. If any signs of deterioration or respiratory fatigue, early intubation and mechanical ventilation are recommended. Maintain oxygenation saturation 92–96% and set positive end-expiratory pressure (PEEP) to at least 5–10 cmH_2O. If patient is severely hypoxic, higher PPEP 15–20 cmH_2O is required. Gastric tube is placed to for gastric decompression. In prehospital setting, peripheral venous access is the preferred route for drug administration. Rapid crystalloid infusion can be considered in case of hypotension if not corrected by adequate ventilation and oxygenation and continued if transfer time is prolonged. Use of norepinephrine and epinephrine dose of 1 mg can be used but higher dose can be used (though controversial), if usual recommended dose is not effective due to mechanism of cardiac arrest due to hypoxia and hypothermia. Monitoring device such as electrocardiograph, $ETCO_2$, and echocardiography is used to confirm the vital parameters. Follow standard advance life support protocol, if patient is in cardiac arrest.

At any point of time, it is very difficult to decide when to stop resuscitation, no factor/factors predict good or poor outcome. It is advised to continue basic life support till signs of life reappear, rescuers are exhausted, or advanced-cardiac life support team is available to take over. Continue advanced life support till patient rewarmed, asystole persists >20 minute, or rigor mortis, and putrefaction. The primary cause of morbidity and mortality in drowning is hypoxia. In addition, the actual volumes of water commonly aspirated are much smaller than originally postulated. Therefore, a resuscitative strategy focused on expelling water from the lungs, instead of reversing hypoxia, will do more harm than good.

In general, all drowning patients should receive initial resuscitative efforts. In general, a submersion time >10 minutes or resuscitation time >25 minutes has been shown to correlate with death or survival with poor neurologic outcome. If there is high suspicion for cervical spine injury (witnessed diving or fall from height, known ethanol ingestion, facial trauma), appropriate precautions should be taken with in-line stabilization, application of cervical collar as long as it does not delay intubation.

Emergency Department Care

The patient of drowning may present with wide range of symptoms. Patient may be completely asymptomatic, or may present with mild cough dyspnea or pulmonary. Patient may

be confused or present with coma. Patient may present in emergency department in cardiac arrest state.

Majority of the person aspirates only small amount of the water and they recover in short period of time. And small section of the drowning person 5–7%% who are rescued by the lifeguards needs hospitalization. Thermal protection should be provided to the drowning person once the measures described in resuscitation section (secure airway, improve oxygenation, and gastric tube) are in place.

In emergency department physical examination, chest X-ray arterial blood gases analysis should be performed. Detail history along with precipitating risk factors such as trauma, seizure, or cardiac arrhythmia should be noted. Measurement of hematocrit, urea nitrogen, and electrolytes is usually inconclusive. Electrolyte disturbance is of no clinical relevance in either salt or fresh water drowning and needs no treatment. In majority of patient, metabolic acidosis (routine use of bicarbonate not recommended) is corrected spontaneously by patient effort to increase his minute ventilation or set the increased minute ventilation or higher peak inspiratory pressure in mechanical ventilation. Toxicological evaluation and computed tomography of head and neck can be considered in specific situation.

Rescued patient can be safely discharged if maintaining good arterial oxygenation without any adjuvant therapy. Patient with grade 2–6 and multisystem involvement need hospitalization and management in intensive care as described in **Table 2**.

Treatment in Intensive Care Unit

Respiratory System

As discussed in pathophysiology section, the predominant changes in the lungs are surfactant dysfunction, alveolar collapse, atelectasis, and intrapulmonary shunting. Severity of illness is ranging from mild self-limiting illness to severe hypoxia and severe acute respiratory syndrome (ARDS). Lung protective ventilation strategies as used in ARDS are beneficial. Even if drowning person is maintaining adequate gas exchange, it is advisable not to wean patient from

TABLE 2: Grading for drowning patient - disposition and management plan.

Grade	***Rescue/Grade 1***	***Grade 2***	***Grade 3***	***Grade 4***	***Grade 5***	***Grade 6***
Prehospital evaluation	*Responsive*	*Responsive*	*Responsive*	*Responsive*	*Nonresponsive but pulse present*	*Nonresponsive but pulse absent*
Clinical presentation	Without cough/ cough	Crepitations/ rales in few lung fields	Crepitations/rales in all lung fields (acute pulmonary edema) with normal blood pressure	Crepitations/rales in all lung fields (acute pulmonary edema) with hypotension/ shock	Unconscious Usually post-CPR revival (ROSC)	If submersion time >1 h (evidence of death →Death → follow forensic procedure If submersion time less than 1-hour CPR if ROSC follow as mentioned below
Interventions	None/oxygenation or monitoring may not be required	Vital monitoring chest X-ray	Vital monitoring electrolytes hemogram, coagulation profile, chest X-ray, high-flow oxygen by face mask/NIPPV	Vital monitoring electrolytes hemogram, coagulation profile, chest X-ray, high-flow oxygen by face mask/NIPPV	Vital monitoring electrolytes hemogram, coagulation profile, chest X-ray	Vital monitoring electrolytes hemogram, coagulation profile, chest X-ray
Further management	None	Low-flow oxygen	Orotracheal intubation and mechanical ventilation	Orotracheal intubation and mechanical ventilation + PEEP, crystalloid and vasopressors infusion	Orotracheal intubation and mechanical ventilation+ PEEP, crystalloid and vasopressors infusion	Orotracheal intubation and mechanical ventilation+ PEEP, crystalloid and vasopressors infusion
Disposition	If no significant history or risk factors can be discharged from incident site	• Observe in ED for 4–6 h • Discharge with pre-caution	Admission and treatment in intensive care unit	Admission and treatment in intensive care unit	Admission and treatment in intensive care unit	Admission and treatment in intensive care unit
Survival	100%	99%	95–96%	75–85%	55–75%	5–10%

(CPR: cardiopulmonary resuscitation; ED: emergency department; NIPPV: noninvasive positive pressure ventilation; PEEP: positive end-expiratory pressure; ROSC: return of spontaneous circulation)

mechanical ventilation at least for 24 hours. In early weaning situation, local pulmonary injury may not resolve adequately pulmonary edema recur and reintubation needed and patient needs hospitalization for longer period of time. Corticosteroid is not much beneficial in reducing lung injury but is helpful in bronchospasm along with bronchodilators.

Early radiographic appearance of opacities is usually misdiagnosed as pneumonia and prophylactic antibiotics are not useful as this adds more resistant and aggressive organism. Early-onset pneumonia can be due to drowning in polluted water and aspiration of gastric contents, so better to monitor the patient on daily basis with patient's temperature pattern, total leukocyte count, culture and sensitivity, response of sputum, and tracheal aspirates, if any new pulmonary infiltrates on serial chest X-rays. Bronchoscopy may be used to clear the mucus plug and also monitoring the lung infections.

Prolonged mechanical ventilation also increases the risk of nosocomial pneumonia and is usually diagnosed on third or fourth day of hospitalization. Once the diagnosis of pneumonia is confirmed, empiric broad spectrum antibiotics, covering both gram-negative and gram-positive organism, should be started and definitive antibiotic after confirmation of organism by culture and sensitivity test.

In few patient (refractory cardiac arrest, submersion in ice cold water), pulmonary function deteriorates and refractory hypoxemia develops, in these patients, extracorporeal membrane oxygenation (ECMO) is helpful in maintaining the oxygenation.

Treatments under investigations for critically ill patients and not recommended now are artificial surfactant, inhaled nitric oxide, and partial liquid ventilation with perfluorocarbons.

Circulatory System

Rescued drowning person can present as cardiac dysfunction and hemodynamically instability, which is usually become normal after correcting hypoxia, rapid crystalloid infusion. Echocardiography can be performed, if these measures do not restore hemodynamic stability and decision can be taken to start inotropic vasopressors or both.

Neurologic System

One of the most worrisome outcomes after drowning resuscitation is permanent neurologic damage which is primary determined by duration of hypoxia. Immediate neurologic assessment and care should be started, if patient is comatose after rescue. Maintain normal level of blood glucose, adequate oxygenation. Maintain neuroprotective hypothermia between 32°C and 34°C for 24 hours. Therapeutic hypothermia has been shown to be of benefit in cardiac arrest, and case reports have suggested similar outcomes for victims of submersion. This should be initiated only after proper resuscitation, with a focus on ventilation, and only in facilities with the proper policies, equipment, and training to initiate and maintain the hypothermia for 24–48 hours.

COMPLICATIONS

Drowning patient may present with multisystem involvement as shown in **Table 3** and should not be misinterpreted as infection. After first 72 hours of resuscitation, features of sepsis and disseminated intravascular coagulation are possible. Renal insufficiency or failure is reported due to hypoxia shock myoglobinuria or hemoglobinuria.

TABLE 3: Multisystem involvement in drowning.

Organ system	*Effects*
Pulmonary	Pulmonary edema ventilation perfusion (V/Q) mismatch and acute respiratory distress syndrome (ARDS)
Neurological	Hypoxic encephalopathy, traumatic brain injury, and spinal injury
Acid-base	Metabolic acidosis
Cardiac	Decrease cardiac output, dysrhythmias, and infarction
Renal	Azotemia

PROGNOSIS

The most consistent prognostic indicator found in the literature is duration of submersion, and this highlights the pivotal role that hypoxia plays in the injury process. Other factors that have been found to have some prognostic value are–delay in initiation of CPR, delay in arrival of emergency medical services (EMS), need for prolonged resuscitation, low Glasgow coma scale score (≤5), pH <7, and asystole on arrival to the ED.

PREVENTION

Expert and research studies suggest following measure to prevent the drowning:

- Unnecessary accumulated water should be drained from bucket pond.
- Apply flood control measures in flood prone area
- Mandatory fencing and rules for swimming pools
- Apply safety signs and warning flags
- Encourage to learn swimming and water safety skills
- Swim in area with life guards and swim with others
- Do not swim after taking alcohol
- Use of grills over water well
- Constant and closely supervise children who are near water
- Learn about use of life jacket and about first aid CPR

SUMMARY

According to WHO, drowning is the second most common cause of unintentional death after road traffic accident. Estimated problem is even bigger as data are not available or unreliable from most of the countries. Drowning problem is more common in children aged 1–14 years and male persons. Alcohol and epilepsy are important risk factors for drowning. Drowning associated with multiple complications such as ARDS, renal failure, and hypoxic encephalopathy. Management (summarizes in **Flowchart 3**) includes CPR, and intensive care unit management including therapeutic hypothermia and ECMO. Prevention is important aspect to decrease the morbidity, mortality, and economic burden on the society.

243
CHAPTER

High-altitude Emergencies

Eric Revue, Anthony Chauvin

INTRODUCTION

In the realm of high-altitude medicine, the term high altitude refers to terrestrial elevations over 1,500 m (4,921 ft), and is commonly divided into three categories—(1) High altitude, (2) Very high altitude, and (3) Extreme altitude. High-altitude emergencies refer to pathologies related to hypoxia increasing with altitude. These pathologies, of which there are three types—(1) Acute mountain sickness (AMS), (2) High-altitude cerebral edema (HACE), and (3) High-altitude pulmonary edema (HAPE). They are of varying degrees of severity but require rapid treatment, otherwise they can become fatal. Around one-quarter of people suffer to AMS at moderate altitude and this proportion up to 50/85% at >4,000 m. The incidence of HACE and HAPE estimates at 0.1–0.4%. This chapter focuses on recent advances in the prevention and treatment of these conditions.

PATHOPHYSIOLOGY AND ACCLIMATIZATION

Acute high-altitude illness is arbitrary classified as high above 1,500 m but symptoms are more common above 2,500 m. Risk factors for developing high altitude are:

- *Individual*: Women, people younger than mid adulthood, history of migraine, obesity, coronary heart disease, and permanent resident <900 m
- *Altitude*: Poor acclimatization, rate of ascent, absolute change in altitude, and altitude >4,000 m

To minimize hypoxemia due to altitude and maintain a normal cellular despite decreased the partial pressure of oxygen (PO_2), an elevation by step is required. The process of acclimatization is complex and incompletely understood. Recommendations stats that people need to stop ascension as soon as he feels symptoms of AMS and stay several days at this altitude. Preacclimatization affords some protection against high-altitude illness. A graded ascent (rest day every 600–1,200 m) and a slow ascent rate (maximum 600 m/day) should allow adequate time for acclimatization and are associated with a lower incidence and severity of illness on ascend.

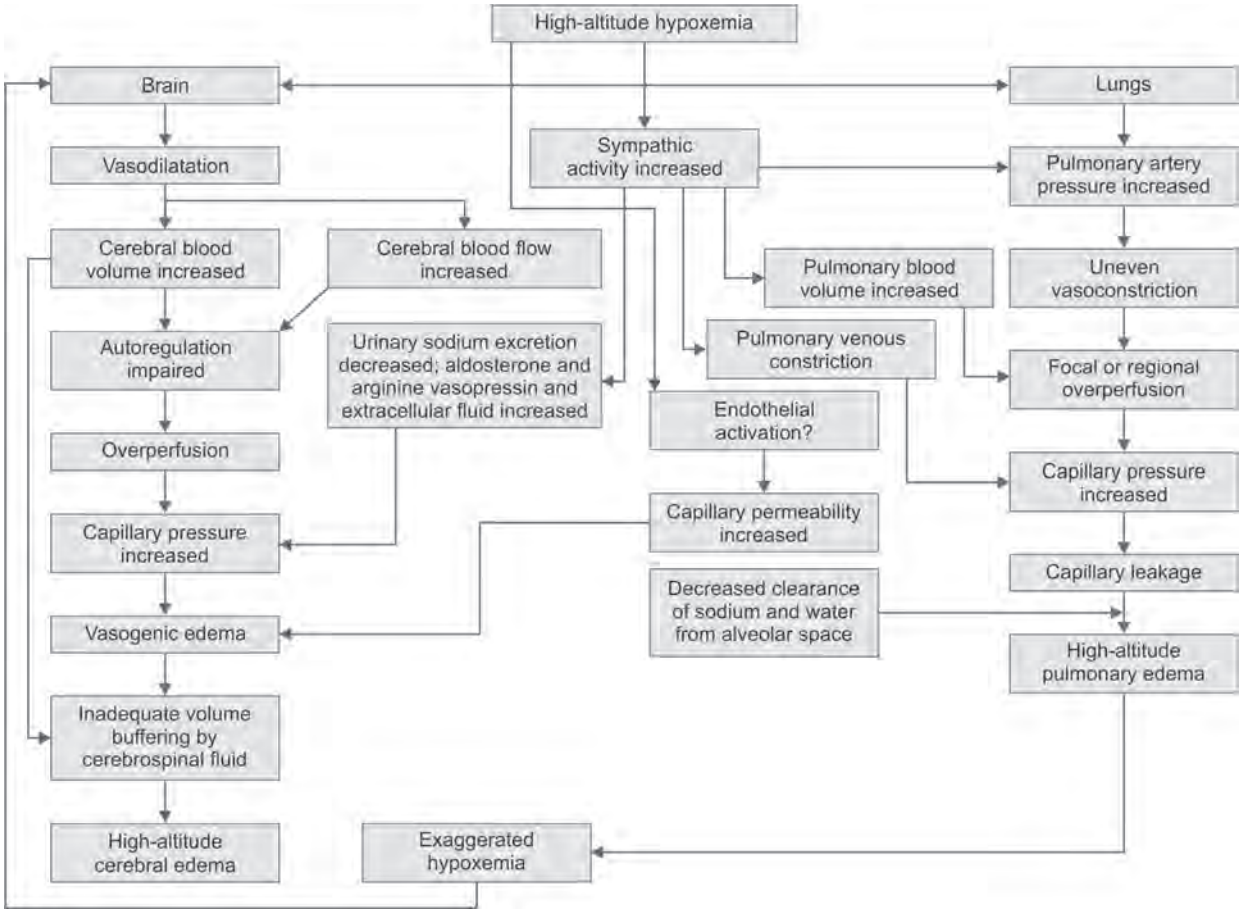
Acute mountain sickness is the clinical manifestation of inadequate acclimatization and hypoxemia induced by the reduction of partial pressure if oxygen, inspired O_2, alveolar O_2, arterial blood oxygen, and so arterial oxygen saturation. Pathophysiologic changes of high altitude which leads to HACE and HAPE are depicted in **Flowchart 1**.

ACUTE MOUNTAIN SICKNESS

Acute mountain sickness is a multisystem disorder with prominent neurological features characterized by headache, and fatigue, anorexia, nausea, or vomiting; fatigue or weakness; dizziness or lightheadedness; or insomnia. Headache is the more common symptom. The diagnosis of AMS is clinical; no diagnostic modalities or physical findings can reliably confirm the diagnosis. Symptoms generally occur at elevations above 2,500 m (8,202 ft) but sometimes occur at as low as 2,000 m (6,562 ft). These nonspecific symptoms may easily be mistaken for a variety of other conditions, particularly in the setting of comorbid illness or the extremes of age. Symptoms of AMS typically develop 6–10 hours after ascent but could appear as earlier (i.e., 1 h). Onset beyond 3 days at a given altitude, the absence of headache, or the lack of rapid response to oxygen or descent suggests other diagnoses. Subarachnoid hemorrhage, intracranial mass, migraine, dehydration, exhaustion, carbon monoxide exposure, substance abuse, and alcohol hangover, among others, are diagnoses that must be considered in the early evaluation of possible AMS. The severity of AMS can be graded using the Lake Louise Questionnaire (**Table 1**).

Treatment

- *Nonpharmacologic*: First of all, the prevention is important—avoid alcohol and sleeping medications. In case of mild AMS, avoid further ascent until symptoms resolved. Acclimatization for 1–2 days at the same altitude is recommended. Hydration by water and reducing activity level could help the patient. In case of moderate or severe AMS, the patient must descend at less altitude.
- *Pharmacologic*: In case of mild AMS, consider classical analgesics and antiemetics. In case of moderate or severe



FLOWCHART 1: Pathophysiologic changes in high-altitude illness.

TABLE 1: Severity of acute mountain sickness.

Symptoms		*Points*
Headache	• No headache	0
	• Mild headache	1
	• Moderate headache	2
	• Severe headache incapacitating	3
Gastrointestinal symptoms	• No gastrointestinal symptoms	0
	• Poor appetite or nausea	1
	• Moderate nausea or vomiting	2
	• Severe fatigue/weakness, incapacitating	3
Fatigue and/or weakness	• Not tired or weak	0
	• Mild fatigue/weakness	1
	• Moderate fatigue/weakness	2
	• Severe fatigue/weakness, incapacitating	3
Dizziness/ lightheadedness	• Not dizzy	0
	• Mild dizziness	1
	• Moderate dizziness	2
	• Severe dizziness, incapacitating	3
Difficulty of sleeping	• Slept as well as usual	0
	• Did not sleep as well as usual	1
	• Woke up many times, poor night's sleep	2
	• Unable to sleep	3
• Mild AMS—A Lake Louise score of 5 or less • Moderate-to-severe AMS – A make Louise Score of 6 or more		

AMS, consider dexamethasone (4 mg every 6 h); and/or acetazolamide (250–500 mg/day/os); if unable to descend, vigilant observation for deterioration; oxygen (1–2 L/min) and/or portable hyperbaric therapy (2–4 psi) for a few hours if available. The hospital care is based on the same recommendations.

HIGH-ALTITUDE CEREBRAL EDEMA

Diagnosis

High-altitude cerebral edema is preceded in major case by symptoms of AMS and is considered the end stage of AMS. HACE can present 3–5 days after arrival to elevations as low as 2,750 m (9,022 ft) but is most commonly seen in remote environments well above this altitude, where the onset of symptoms may be much more abrupt over a period of hours. The diagnosis is clinical and based on altered sensorium and ataxia. Mental status changes may include irrational behavior that rapidly progress to lethargy, obtundation, and coma. If untreated, death results from brain herniation.

Treatment

Treatments are immediate descent or evacuation at 1,000 m (3,281 ft), oxygen to maintain SaO_2 >90%, and dexamethasone (8 mg IV/IM/PO initially, then 4 mg per 6 h). If descent is not an option, one may use a portable hyperbaric chamber and/or supplemental oxygen to temporize illness, but this should never replace or delay evaluation/descent when possible.

HIGH-ALTITUDE PULMONARY EDEMA

Leakage of the pulmonary blood gas barrier leads to accumulation of fluid in the lungs. In high-altitude, pulmonary vasoconstriction occurs and pulmonary hypertension occurs in all individual. HAPE should be differentiated from asthma, bronchitis, heart failure mucus plugging, myocardial infarction, pneumonia, and pulmonary embolus.

Diagnosis

Manifestations of HAPE include decreased exercise tolerance and a prolonged recovery period after exertion at altitude. Dyspnea, chest discomfort, and dry cough are frequent. In severe cases, the physical examination reveals tachycardia and tachypnea. Auscultation reveals rales, often asymmetrical in distribution, and usually found in the right mid-lung initially. Cyanosis and orthopnea may become prominent in severe cases. The electrocardiogram could report sinus tachycardia and may suggest acute pulmonary hypertension (i.e., right axis deviation, right bundle branch block, right ventricular hypertrophy by voltage, and right atrial enlargement). Hemodynamic measurements reveal high-pulmonary artery pressure and pulmonary vascular resistance, as well as low to normal pulmonary wedge pressures, cardiac output, and systemic arterial blood pressure.

Treatment

The treatment is based on oxygen (4–6 L/min until improved, then 2–4 L/min to conserve supplies and maintain SaO_2 >90%); minimize exertion and keep patient warm; descend or evacuate at 500/1,000 m (1,640–3,281 ft) as soon as possible; if descent/O_2 unavailable, portable hyperbaric therapy may be lifesaving; consider nifedipine (10 mg PO, then 30 mg extended-release PO q 12–24 h) if no HACE; consider inhaled beta-agonists (salmeterol, 125 lg inhaled per 12 h, or albuterol); consider EPAP mask; dexamethasone only if HACE develops.

PREVENTION OF HIGH-ALTITUDE ILLNESS

Optimize acclimatization is the primary goal to prevent the illness. Recognize the illness early stage and treat correctly. Avoid ascend to higher altitudes if symptoms persist. Start treatment measures, if symptoms do not improve despite pharmacologic therapy, descend to lower altitude. In the presence of confusion, ataxia, or dyspnea at rest with relative hypoxemia, descend and/or treat immediately with definitive therapy. For all forms of altitude illness, descent is the definitive treatment. But due weather and logistic constraint descend is not always possible. Although prevention and treatment strategies are organized into pharmacologic and nonpharmacologic approaches, in clinical practice these strategies are often combined for best results. **Table 2** summarizes the pharmacologic approach for prevention and treatment of high-altitude illness (HAI), including newer strategies.

SUMMARY

Acetazolamide remains the best choice for prevention of AMS. The best treatment for all HAI is descent or oxygen, or both. Dexamethasone is excellent for treating moderate to severe AMS, and for HACE. First-line therapy for HAPE supplemental oxygen; if oxygen is not available descent is primary therapy. Combined measures, e.g., oxygen and descent are more effective than drug therapy. Definitive treatment for HACE is descent and should not be delayed. Important adjunctive treatments for HACE are dexamethasone and supplemental oxygen until descent can be facilitated.

TABLE 2: Drug therapy for high-altitude illness.

Drug	*Indications*	*Doses*	*Adverse effect*	*Comments*
Acetazolamide	Prevention of acute mountain sickness	125 mg every 12 h. Begin 24 h before ascent. Continue for at least 48 h after arrival at highest altitude	*Common*: Paresthesiae, polyuria, altered taste of carbonated beverages *Less common*: Nausea, fatigue, and headache *Rare*: Stevens-Johnson or anaphylaxis	Enhances acclimatization; pregnancy category C; avoid if breastfeeding
	Treatment of acute mountain sickness	250 mg PO every 12 h		
Dexamethasone	Treatment of acute mountain sickness	4 mg every 6 h PO, IM, or IV	*Common*: Mood changes, insomnia, and dyspepsia *Rare*: Adrenal suppression, psychosis, and hyperglycemia	Rapidly improves AMS symptoms, beware minor rebound symptoms; lifesaving in cases of HACE; pregnancy category C
	High-altitude cerebral edema	8 mg initially, then 4 mg every 6 h PO, IM, or IV		
Ibuprofen	Prevention of acute mountain sickness?	600 mg every 8 h during ascent	Dyspepsia; exercise-induced kidney injury	Risk of gastrointestinal bleed
Budesonide	Prevention of acute mountain sickness	200 µg every 12 h, beginning 3 d before ascent	Sore throat, myalgias, headache, and oral candidiasis	Vastly more expensive than acetazolamide or dexamethasone; optimal regimen needs validation

Continued

Continued

Drug	*Indications*	*Doses*	*Adverse effect*	*Comments*
Tadalafil	Prevention of high-altitude pulmonary edema	10 mg PO every 12 h starting 24 h before ascent. Continue for 2–4 d at max sleeping altitude	*Common*: Headache, facial swelling *Rare*: priapism	BID dosing, compared with TID dosing with sildenafil; fewer side effects, less hypotension when compared with nifedipine; pregnancy category B
Nifedipine	Prevention of high-altitude pulmonary edema	30 mg extended release, PO every 12 h, starting 24 h before ascent	Reflex tachycardia, hypotension (uncommon)	Pregnancy category C; Not necessary, if oxygen available
	Treatment of high-altitude pulmonary edema	30 mg extended-release PO every 12 h

244
CHAPTER

Electrical and Lightning Injuries

Neeraj Mangla, Sahanya Ramesh Shetty

INTRODUCTION

Electrical injuries are caused due to contact of human body with electric current. This produces heat energy disseminated onto the skin surface superficially and transmitted internally throughout the body. Though, they account for a lower incidence, there is a high risk and fatality associated with it. The injury sustained affects multisystem increasing risks of morbidity and mortality. Factors determining the magnitude of injury include:

- Resistance offered by the victim
- Voltage source
- Course traversed by the electric current
- Time frame of contact

ETIOLOGY

Majority of the cases include contact with household appliances or occupational hazards. Predisposing risk factors can be distributed among the infants in contact with household cables, adolescent boys playing near or around exposed high-voltage current sources and adults handling heavy duty wires and cables daily at their workplace.

- *Low-voltage injuries (<600 V)*: It is usually caused by alternating current, where the victim is unable to let go easily. This causes prolonged contact with the source and greater degree of superficial burns and cutaneous injuries (**Figs. 1A** to **C**). *Note: Rhabdomyolysis and secondary trauma are uncommon.*
- *High-voltage injuries (>600 V)*: These are predisposed by either alternating or direct current. Injuries involve deep second-degree burns. Trauma occurs due to tetany and fall from height. Contact is usually brief with rhabdomyolysis.

PATHOPHYSIOLOGY

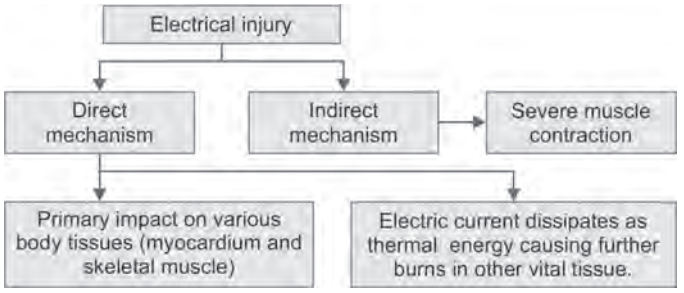
Degree of electric burns depends on the strength of the electric current passed into the patient.
According to Ohm's law,

$$\text{Electric current } \alpha \frac{\text{Voltage of the source}}{\text{Resistance}}$$

FIGS. 1A TO C: (A) "Flashover effect" over the posterior aspect of arm and forearm; (B) Superficial burns sustained after an electrical injury over lateral aspect of chest and abdomen; (C) Hyperpigmented skin with superficial burns. ***(For color version, see plate 51)***
Courtesy: Dr Gaurav B Shetty.

The extent of injury caused will be different in different parts of the body even with the same voltage, since resistance across tissues is varied. Resistance across tissues is as follows:

Highest resistance is seen in fat, tendon, and bone, followed by skin. Least resistance: Nerves, blood vessels, and muscles. Tissues with moisture (like muscles) have decreased amount of resistance than tissues with no moisture (like skin). Higher resistance by the skin offers to more diffuse burns, while lower resistance by skin can cause deeper burns, affecting vital visceral organs (**Flowchart 1**). Be it dry or moist, electrical energy passes through highly resistant skin and disperses through tissues with lesser resistance easily. As a result, burns appearing mild on the surface may have deranged underlying



Electrical injury
Direct mechanism
Indirect mechanism
Severe muscle contraction
Primary impact on various body tissues (myocardium and skeletal muscle)
Electric current dissipates as thermal energy causing further burns in other vital tissue.

FLOWCHART 1: Algorithm portraying electrical current pathophysiology.

TABLE-1: Physiological changes corresponding to varied intensity of currents.

Intensity of current (IN mA)	*Physiological changes*
1	Not perceptible—mostly tingling
7–9	"Let-go" for an average man
6–8	"Let-go" current for an average woman
3–5	"Let-go" current for an average child
16–20	Tetany of skeletal muscles
20–50	Paralysis of respiratory muscles; respiratory arrest
50–100	Threshold for ventricular fibrillation
>2	Asystole

tissues. The electric current at which removal of the electrical source is barred due to tetany (muscle contraction) is the let-go threshold (**Table 1**).

Direct Contact

The mechanism of electrical injuries involves heating up of tissues from skin at the superficial layers to deeper tissues causing electrothermal burns. Primarily affected areas will be those in contact to the source point with the ground. The extent of organs involved during the transitory course of current (entry to exit) helps in estimation of the magnitude of the injury and prognosis of patient. Any trail of current in line with the vertical axis of the body is risky as it indirectly affects the myocardium, muscles for respiration, central nervous system (CNS), in cases of gestational mothers—uterus, and viable fetus. Horizontal course of current: It affects the cardiopulmonary system and musculoskeletal system and spares the CNS. *Mechanism of injury in cardiac tissue involves in either of the two pathways:*

1. *Tissue damage of myocardium leading to necrosis*: Majority of the cases show presence of widespread, patchy band like necrosis including the coronaries, myocardium, right and left conduction pathways, and the nodal tissue. In high-voltage injuries, the smaller vessels are likely to be more damaged due to coagulation necrosis. This may further develop into compartment syndrome in cases of injuries to vascular territories in extremities that dampen the overall circulation.

FIGS. 2A TO C: Deep burns over posterior aspect of thigh and posterior gluteal region. ***(For color version, see plate 51)***

Courtesy: Dr Gaurav B Shetty.

2. *Cardiac arrhythmias*:
   - *Current coursing through lower limbs*: It might involve soft tissues around the point of contact, hence may not be life threatening but definitely limb threatening.
   - *Electrical arcs*: An electrical arc can produce temperature up to 2,500–5,000°C that results in deep thermal burns (**Figs. 2A** to **C**) at the surface of the skin. Arcing current causes direct tissue damage by exposure to ionized superheated air, which are typically skin burns. High-voltage injuries can cause thermal as well as flame burns, along with effects of direct electric current along the arc pathway.
   - *Flame*: Incineration of clothing can cause direct burns through flames. Electrothermal and arcing current result in incineration of clothing.

CLINICAL MANIFESTATIONS

Cardiovascular System

- Ventricular fibrillation and cardiac standstill (PEA—pulse less electrical activity/asystole) are the most fatal and dreaded complications in early management.
- Most common changes in cardiac activity include sinus tachycardia (>150 bpm) and ventricular arrhythmias.
- *Other defects in conduction pathways*: Bundle branch blocks, atrioventricular blocks, and QT interval prolongation are also common.
- Supraventricular tachycardias and atrial fibrillation
- Necrosis and thermal burns of myocardium may cause infarction, pericardial injury, and heart failure.

Respiratory System

Clinical presentation involves either direct impact on respiratory center leading to respiratory arrest or due to suffocation

attributed to the contraction of respiratory muscles involved in the pathway of electric current. Respiratory failure initially presents due to underlying cardiac arrest.

- Toxic inhalation of carbon monoxide or other substances can cause thermal burns of passages within the airway. Chemical toxins (ozone) can cause mucous membrane irritation, decreased pulmonary function, and alveolar hemorrhage.
- *Complications*: Pneumonitis, pulmonary effusion, hypoxia due to direct CNS dysfunction, fluid shifts causing edema, pain, ventilator-associated pneumonia, acute respiratory dysfunction syndrome secondary to excessive fluid resuscitation, and/ or ischemia
- *Late findings*: Pulmonary embolus may develop from underlying deep venous thrombosis (DVT) due to immobilization of limbs, or due to fractures of long bones.

Renal System

Due to vascular damage, kidneys are at high risk for ischemic injury. Resultant effect may cause thrombosis and vasoconstriction of blood vessels. In addition, excessive myoglobin released may lead to myoglobinuria. This leads to a progression toward acute kidney injury and renal failure.

Skeletal System

Muscular contraction is caused by tetany, producing rhabdomyolysis, orthopedic injuries, and necrosis of muscles. Prolonged time of contact with source causes deeper tissue damage. Patients may have multiple sequelae such as burns, fractures which may be masked and missed out during initial assessment. Limited range of motion and deformities respective to joints are signs of possible underlying fractures (**Figs. 3A** to **C**).

- *Compartment syndrome*: Patient with high-voltage injuries is more prone to compartment syndrome even with a contact <1 second. Patients typically present with ongoing muscle pain and pain on muscle movement (**Figs. 4A** to **C**).
- *Vascular injury*: Electric current passing through extremities may cause spasm in peripheral arteries, thrombosis, and/ or aneurysm formation. Extensive injury to vascular system may lead to rhabdomyolysis or compartment syndrome. High-voltage injuries (>600 V) associated with multiple crush injuries, extensive burns, and cardiopulmonary arrest lead to myoglobinuria, elevated creatine phosphokinase (CPK) level, elevated serum myoglobin level, and urine dipstick positive for blood. Acute limb ischemia may present due to thrombosis. Risks of DVT are increased in patients, since they are immobilized due to morbid injuries or possible surgeries.

Central Nervous System

- Transient loss of consciousness, coma, convulsions, agitation, quadriplegia, hemiplegia, and visual disturbances are most common symptoms seen in high-voltage injuries. Head computed tomography (CT) is indicative of any intracranial injury.
    - Spinal cord injuries are primarily due to vertebral fractures occurring at multiple levels. Magnetic resonance imaging (MRI) study may not completely correlate with clinical picture of patient in electrical injury. Mortality increases in cases of extension of the cord dysfunction to the brain stem.
- Signs of a basilar skull fracture (postauricular ecchymosis, hemotympanum, and clear nasal drainage), cervical injury
- Peripheral nerve damage or permanent weakness in extremities may present with transient paresthesia or delayed onset of the same. Peripheral nerve damage may occur in trivial electrical burns. Contact with the electric current may cause median or ulnar neuropathy more often than radial neuropathy.
- High-voltage injuries produce cutaneous burns as entry and exit wounds (**Fig. 5**). Severely injured patients may present with burns on the palms, feet, and on the skull.

Other Clinical Features

- *Fixed and dilated pupils*: Due to traumatic brain injury as a result of fall also cerebral tissue damage due to direct pathway of electric current, or as a result of death in some cases.

FIGS. 3A TO C: Comminuted fracture over the distal metacarpal bone.

- Low-grade intravascular coagulation supervenes due to hypoxia, rhabdomyolysis, and release of procoagulants from tissue damage.
- If the patient has come in contact with a DC source, there will be burns visible at the sites of entry and exit. However, when in contact with AC source, due to its cyclic movement there may be no distinct or evident entry and exit point.
- In 50% cases, tympanic membrane may rupture causing temporary sensorineural hearing loss. Complications with a delayed onset include mastoiditis, sinus venous thrombosis, meningitis, and brain abscess. Hearing should be briefly checked in the ED with regular follow-up of a patient with hearing deficits.
- Injuries to visceral organs include bowel perforation and intra-abdominal hemorrhage, whaich areseen in high-voltage injuries.
- Cataracts usually present as a common complication after lightning injuries (rarely acutely). Retinal detachment, corneal burns, intraocular hemorrhage, and intraocular thrombosis are also present in high-voltage injury.

EVALUATION OF ELECTRICAL INJURIES

Initial assessment and resuscitation include securing airway, breathing, and adequate circulation along with acute management of multiple traumas. Treatment module should generally follow along the same guidelines of pediatric and adult resuscitation as for any other traumatic injury.

History

Acquire details of events leading to accident, time span of contact, type of current, sustained fall from height, physical environment, and underlying medical conditions.

Investigations

Complete analysis of magnitude of injury is essential for better prognosis. Complete blood count, serum electrolytes, sequential evaluation of liver, and pancreatic and renal function are essential to rule out ischemic vascular changes and possible renal or liver failure electrocardiogram (ECG) with routine cardiac monitoring, and troponin levels. Elevated Serum myoglobin, blood urea nitrogen, creatinine level, and creatine kinase (CK) give an early indicator of rhabdomyolysis. Early analysis of urine for myoglobinuria may indicate rhabdomyolysis.

Creatine kinase-muscle/brain (MB) and troponin might be elevated in electrical burns, especially when pathway of current is through thoracic trunk. Brain natriuretic peptide (BNP) may also be raised in some cases.

Metabolic changes can be estimated with arterial blood gas values. Ophthalmic and otoscopic assessment is done for signs of tympanic membrane rupture, ocular nerve damage, mastoiditis, sinus thrombosis, retinal detachment, corneal burns, or intraocular thrombosis. Precautionary treatment is done for stress ulcers in stomach. A pregnancy test is mandatory in all women of childbearing years. Psychiatry consultation is necessary immediately after patient regains consciousness and is stable.

Imaging

Evaluation of the chest, abdomen, thoracic, head, spinal, and pelvis for trauma should be performed according to trauma guidelines.

- CT scan/MRI brain—in cases of severe traumatic brain injury following fall from a height and abnormal neurological findings
- Evaluation with a FAST (focused assessment with sonography in trauma) examination to screen for intra-abdominal injuries/hemorrhage
- Radiological studies—in order to rule out possible fractures and/or dislocations, X-ray can be done.

Special Considerations

It is of no doubt that care should be availed immediately, however, one must assure that the patient has been completely separated from the point source of electric current prior to any treatment and/or being moved away safely with the help of insulated equipment. In contrast to electrical injury, rescuer is not susceptible to any harm or danger when in contact with a patient of lightning injury; hence treatment can be started immediately.

- *Pregnant patients (20–24-week gestation):* Additional measures have to be taken to monitor fetal heart rate and uterine activity for up to 4 hours due to mechanical injuries caused by electrical trauma. Patient should be asked about use of seatbelt during a motor vehicle accident, along with episodes of fainting, pain, last menstrual pain, gestational age of fetus, any p/v bleed or discharge and/or presence of fetal movements. Monitoring of viable fetus with no signs of distress is essential with the use of fetal Doppler ultrasound and an external transducer to detect uterine contractions. Physical examination should include abdominal tenderness and evaluation for any orthopedic injuries. In cases of premature labor induced, tocolytic therapy should be started. In cases with fetal distress, cesarean delivery is performed by the obstetrician.
- *Children*: Children (aged <5 years) who inadvertently place end of a power cord in the mouth produce oral and lip burns. The electric current passed between the cords produces significant tissue damage due to elevated local temperature. Most common sites involve the tongue, lateral commissure, and/or alveolar ridge. In up to 10% cases, bleeding of labial artery occurs when the eschar begins to separate after a few days of the burn. Children with this kind of injury are admitted in the hospital for observation. In some cases, outpatient home care and review is adequate. Proper counseling for parents about possible bleed is essential for up to 2 weeks of incident. Home care involves the use of normal saline for rinsing and gentle wound debridement of necrotic tissue. Specialty consulting is needed for the prevention of deformities and dysfunction. Follow-up and review to maintain local wound care and preventing any infection. Older children have a higher incidence of high-voltage injuries and upper extremity injuries, often requiring fasciotomy or skin grafting.

TREATMENT

Intervention should initiate with securing airway, maintaining breathing, and adequate circulation at the earliest. Administration of oxygen and ventilation should be started immediately in a patient with signs of apnea. Alternative airway such as bougie assistance, video-assisted laryngoscope, and fiber optic equipment should be ready. In adverse cases, cricothyrotomy can be performed under sterile conditions. Stabilization of cervical spine should be maintained in unconscious and/or those that require intubation. It is safe to assume that any patient of electrical or lightning injury may have sustained a spinal cord injury. Hence in all cases, proper head and neck immobilization is essential.

Fluid Management

In cases of severe high-voltage electrical injury, presenting symptoms generally include an amalgamation of considerable visceral injury along with extensive burns. This leads to loss of fluid into third space compartment. An extensive degree of breakdown of muscle causes myoglobinuria, CK, and CK-MB testing can be helpful. CK helps to assess for rhabdomyolysis. A CK-MB >80 ng/mL is predictive of limb amputation. In significant cases, progression to renal failure is noted. Establish intravenous (IV) access and give isotonic fluids to maintain urine output at 1–1.5 mL/kg/h. Obtain an ECG and place the patient on cardiac monitoring. *According to Parkland formula, it is ideal to raise fluid requirement by two times on the basis of burnt surface area***.** Fluid requirement should be calculated from the time of burn. Establishment of an isotonic balanced crystalloid like Ringer's lactate solution for fluid resuscitation is necessary. Keep a note of the urine output on an hourly basis and maintain an output between 0.5 and 1 mL/kg/h in the initial 24 hours.

For correction in serum electrolyte imbalances, start sodium bicarbonate at 1–2 mEq/kg. In cases of high-voltage injuries and larger extent of burns, one is likely to develop severe acidosis and myoglobinuria. Hence an initial bolus of fluids should be administered following a correction by sodium bicarbonate.

In order to increase osmotic dieresis, patient should be started on mannitol at 1 g/kg of body weight. Maintain a urine output at 2–3 mL/kg/h, at a urinary pH above 6.5. Sodium bicarbonate alkalizes the urine; therefore it causes myoglogin to be more soluble. The recognized drug of choice for dieresis is acetazolamide, as it causes alkalization of urine. One of the red flags includes the progression to hyperosmotic hypoalbuminemia. Careful caution in administration of acetazolamide is essential to prevent this.

Initial IV rate in adult is up to 1.5 L/h with close monitoring of urine output in order to decrease the level of serum CK in serum less than five times normal or urine myoglobin level return to normal. It is comprehensible that a urinary catheterization is compulsory for the constant monitoring or urine output. One must also look out for hematuria or dark-colored urine, indicating a possible myoglobin-induced tubular necrosis. This can be treated with an initial bolus of fluids in order to promote dieresis and sodium bicarbonate.

Pain Management

For better pain control, it is advisable to start a short-acting opioid such as fentanyl (1 μg/kg IV), as a continuous infusion and is more easily titratable. In case airway is not secured, it is vital to intubate the patient. Superficial and deep burns need cleaning and dressing under aseptic conditions, along with antibiotic coverage. Update tetanus immunization as indicated. It is evident that in higher percentage of burns, risks of containment of infections are much higher. Use of sterile gowns, gloves, and face masks/shield is important in prevention of nosocomial infections.

In order to prevent acute limb ischemia and compartment syndrome, fasciotomy is indicated in patients with >20% burn surface area, myoglobinuria, and/or full thickness burn over 12% body surface area. Checkerboard escharotomy is required on a patient sustained >50% electrical burns (**Fig. 6**). According to the condition of patient, involvement of general surgeon/orthopedic, neurosurgeon can be helpful in early surgical intervention, if required.

TASER INJURIES

Taser is a device that produces two-barbed projectiles in to the victim's body. There may be an initial 50,000 V shock followed by multiple subsequent shocks. Most injuries are caused due to direct effects of Taser and/or mechanical injuries due to subsequent fall or physical interactions after the act.

FIG. 6: Checkerboard escharotomy done on a patient sustained more than 50% electrical burns. ***(For color version, see plate 52)***
Courtesy: Dr Gaurav B Shetty.

Clinical features: Usually minor
- Fractures and traumatic brain injury
- Injury to eye/testicles
- Pneumothorax
- *Injury to gravid patients*: Monitor fetal heart rate and uterine activity
- Ventricular fibrillation and Taser-induced arrhythmias
- Cognitive abnormalities
- Traumatic injuries from metallic barbs

Approach to such patients should follow the standard guidelines of Advanced Cardiovascular Life Support/Advanced Trauma Life Support (ACLS/ATLS). Chest pain along with shortness of breath is indicative of increase in sympathetic tone. ECG is to study underlying arrhythmia due to stressful event. The main point to be assessed is if the patient is under the influence of alcohol and/or recreational drugs or the patient is suffering from any mental illness. At any event of cardiac arrest, standard ACLS protocol is to be followed.

INJURIES CAUSED BY LIGHTNING STRIKES

In contrast to electrical injury, exposure time to victim is in milliseconds with voltage in millions, ampere in thousands. Hence the total energy transferred is limited. Due to excessive rain accompanying lightning strike, water acts as a conductor of current over the skin producing *"the flashover effect"*. The rapid expansion of air causes concussive blast. These cause a unique pattern of injury over the skin surface. Patients are usually thrown over the ground due to the lightning strike. Types of lightning injuries:
- *Direct strike:* The greater part of the lightning passes directly into the person.
- *Side flash:* It includes a direct strike of lightning to a person and a resultant discharge to a second person in close proximity.
- *Stride potential:* Initially, the lightning strikes the ground then enters the body from one foot and exits from the other.
- *Flashover phenomena*: Lightning current moves along the body, resulting in blast effect on the clothing.

Clinical Features
- Burns can be arc burns, flash burns, superficial, or deeper burns.
- *Lichtenberg figures*: A fine branching rash that resembles branches of tree is unique for lightning injuries. These changes in skin are temporary and superficial, and fade within weeks.
- *Ophthalmic changes*: Retinal detachment and cataracts
- Tympanic membrane rupture
- Sudden death, cardiac arrest, and coronary vasospasm
- *Central nervous system dysfunction*: Immediate or delayed symptoms may present. Ischemic stroke, spinal cord injury, and keraunoparalysis (mimics spinal cord injury) may occur. These patients may develop cerebral salt wasting syndrome, transient or permanent stroke, and/or peripheral nerve lesions.
- *Traumatic injuries*: Spinal cord injury/fractures and skull fractures
- Pinpoint cerebral hemorrhage, ischemia, and infarction
- Myoglobinuria and rhabdomyolysis
- Vasospasm may mimic stroke, myocardial infarction, and bowel ischemia, or cause signs of compartment syndrome.

Management
- *Low-voltage injuries*: Patients with normal ECG, no syncope or arrhythmias and/or minimal superficial burns can be discharged without cardiac monitoring. However, proper counseling about risks of chest pain, agitations, syncope, palpitations, and compartment syndrome should be done. Written follow-up for the same should be provided and arranged with the regional burn center or primary healthcare provider.
- *High-voltage injuries*: Patients with high-voltage injuries should be admitted/referred to a tertiary burn center. Depending upon the type of injuries sustained, orthopedic, ENT, neurologist/neurosurgeon, cardiologist, vascular surgeon, plastic surgeon, and ophthalmologist should be consulted. Prior to transfer to a burn center, initial stabilization is a must, keeping in mind the possible complications after the initial treatment. Therefore, airway, breathing, and circulation should be in control before shifting the patient to the burn unit. This may include fasciotomy or escharotomy, if necessary. The transport of patient should be accompanied by ACLS/Advanced Life Support (ALS) certified paramedics, who are aware of treatment guidelines such as fluid resuscitation, neurological status, and analgesia. Trauma takes precedence over burn patients with severe traumatic injuries will require transfer to a trauma center first.

Management Summary
- Primary and secondary survey as per ACLS/ATLS guidelines
- Airway secured to maintain adequate ventilation
- Intravenous fluid resuscitation
- Electrocardiogram/arterial blood gas/complete blood count (CBC)/CK-MB/serum electrolytes
- Gastrointestinal injury can be assessed better with CT abdomen.
- Repeat neurological examination
- *Magnetic resonance imaging brain*: In order to confirm cerebral hemorrhage, ischemia, and infarction

- Admission to specialized burns intensive care unit
- Consult with plastic surgeons/orthopedics/ENT/ophthalmologist

DISPOSITION

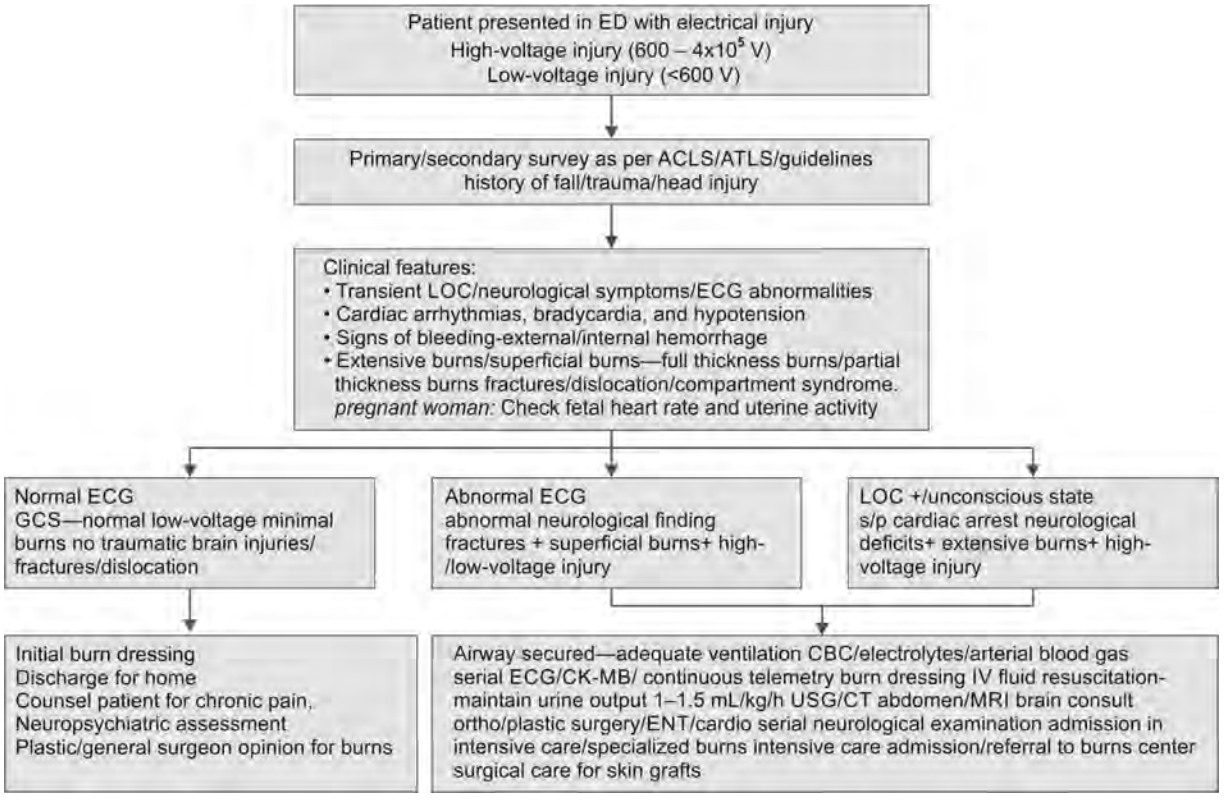
- *Patients suffering low-voltage electrical injuries*: Asymptomatic with no cardiopulmonary arrest, no loss of consciousness, no extensive or superficial burns, and whose neurological examination as well as ECG is normal and can be safely discharged after initial observation. They have to be counseled regarding possible neurological symptoms that may present hours after this accident and to review weekly otherwise.
- *Patients presenting with higher voltage* injuries and/or experienced cardiopulmonary arrest, abnormal neurological findings suggestive of CNS injury and/or spinal cord injury, extensive burns, or vascular damage in extremities, visceral injuries should be transferred in to intensive care unit or to a specialized burns intensive care unit. Indications of admission in electrical and lightning injury are shown in **Box 1**.

SUMMARY

Electrical burns related hospitalization and fatalities in burn centers are mostly occupationally related. Children have a predisposition to injuries from low-voltage sources, such as electric cords, because of their limited mobility within a relatively confined environment. During adolescence, however, a more active exposure to the environment is possible and may lead to more severe high-voltage injuries or death. At the time of presentation, documentation of injuries is important not only for the immediate resuscitation of the victim but also medicolegally. Nearly all cases of electrical injuries eventually involve litigation for negligence, product liability, or worker compensation (**Box 1**). Lightning incidents often include more than one victim when the current "splashes" to other individuals or as ground current spreads the electrical power throughout the area where a large group may be sheltered in a storm. It is not possible to predict the amount of underlying tissue damage or severity, based on the cutaneous involvement. Management approach for electrical injuries is shown in **Flowchart 2**.

BOX 1: Indication for admission in "Electrical" and "Lightning" injury.

- Cardiac arrest
- Documented loss of consciousness
- Abnormal ECG dysrhythmia observed in prehospital or ED setting
- History of cardiac disease
- Presence of significant risk factors for cardiac disease
- Concomitant injury severe enough to warrant admission
- Suspicion of conductive injury
- Hypoxia
- Chest pain



Patient presented in ED with electrical injury
High-voltage injury (600 – 4x10^5 V)
Low-voltage injury (<600 V)
Primary/secondary survey as per ACLS/ATLS/guidelines
history of fall/trauma/head injury
Clinical features:
• Transient LOC/neurological symptoms/ECG abnormalities
• Cardiac arrhythmias, bradycardia, and hypotension
• Signs of bleeding-external/internal hemorrhage
• Extensive burns/superficial burns—full thickness burns/partial thickness burns fractures/dislocation/compartment syndrome.
pregnant woman: Check fetal heart rate and uterine activity
Normal ECG
GCS—normal low-voltage minimal burns no traumatic brain injuries/ fractures/dislocation
Abnormal ECG
abnormal neurological finding fractures + superficial burns+ high-/low-voltage injury
LOC +/unconscious state
s/p cardiac arrest neurological deficits+ extensive burns+ high-voltage injury
Initial burn dressing
Discharge for home
Counsel patient for chronic pain,
Neuropsychiatric assessment
Plastic/general surgeon opinion for burns
Airway secured—adequate ventilation CBC/electrolytes/arterial blood gas serial ECG/CK-MB/ continuous telemetry burn dressing IV fluid resuscitation-maintain urine output 1–1.5 mL/kg/h USG/CT abdomen/MRI brain consult ortho/plastic surgery/ENT/cardio serial neurological examination admission in intensive care/specialized burns intensive care admission/referral to burns center surgical care for skin grafts

(ACLS: Advanced Cardiovascular Life Support; ATLS: Advanced Trauma Life Support; CBC: complete blood count; CT: computed tomography; CK-MB: creatine kinase muscle/brain; ECG: electrocardiogram; GCS: Glasgow coma scale; LOC: loss of consciousness; MRI: magnetic resonance imaging; USG: ultrasonography)

CHAPTER

Snake Bite

Jaideep C Menon, Joseph K Joseph

INTRODUCTION

Snakes are one of the most successful predator species partly because of their tremendous adaptability. Snakes survive on land, in the seas and certain species are arboreal. Snakes are amongst the most adaptive and resilient predators with certain species having adapting to the cold of the arctic, certain to the altitude of the Himalayas, some others to the depths of the oceans, and some others to the harshness of deserts. But most snakes thrive in the tropical rain forests. Snakes have long captured the imagination of humans and have been deified in many of the older civilizations.

EPIDEMIOLOGY

Human beings are not the natural prey of snakes but get bitten accidentally in most cases. Worldwide, there are about 4.5–5.4 million bites estimated every year, half of them leading to envenomation. The largest number of bites occurs in the South-East Asia with about 50,000 people dying of snakebite annually in India alone.

SNAKES

There >3,400 species of snakes of which about 300 are venomous out of which half of them are capable of producing toxicity from their bite. Venomous snakes are broadly classified as elapid, viperids, and some of the colubrid. Snakes have been subclassified as venomous, mildly venomous, and nonvenomous, depending on the presence of venom glands and their delivery apparatus or its absence. Snakes kill their prey either by constricting them to death (e.g., pythons, anacondas, and boa constrictors) or by immobilizing them through the action of venom when injected.

Snakes possess most of the organs that mammals do like the lungs, kidneys, heart, brain, spleen, liver, intestines, etc. The difference being in that all the organs are stretched out usually placed in an anteroposterior position and not side-to-side, the right-side organ generally is larger than the left and in many species the left lung may actually be absent. Snakes have poor visual and auditory function with the absence of an external ear. Snakes compensate for this through it bifid tongue which is capable of picking chemicals from the environment which it then places in the receptacles of an organ at the base of the skull called the Jacobsen´s organ. The Jacobsen's organ is able to analyze the chemical and helps the snake decide if the chemical is that of a possible prey. It is to say that it is nature's ultimate chemical autoanalyzer. The belly scales (ventral scales) of a snake sense vibration which helps them in both avoiding danger as also in the capture of prey. Constrictors generally release their coils once they sense that the heartbeat has stopped which they sense through their ventral scales.

Certain species called the "pit-vipers" have a small circular pit between their eyes and nostrils (**Fig. 1**) which is a heat-sensitive organ able to pick up temperature differences of a fraction of a degree Celsius, thereby helping it spot warm-blooded mammals even in the dark. Arguably it is the presence of venom glands with their delivery system which have given venomous snakes an evolutionary advantage. Venom glands are modified salivary glands whose secretions help the snake both in the capture of prey, by immobilizing it and also in the process of digestion of the prey. Snake venom enzymes and proteins have a strong corollary to human pancreatic ones.

Elapids include species of cobra, king cobra, krait, coral snakes, taipans, mambas, and sea snakes. Terrestrial elapids

FIG. 1: Pit Viper showing pit between the nostril and eyes. ***(For color version, see plate 52)***

have long, slender bodies with smooth scales (**Fig. 2A**), a head covered with large shields (**Fig. 2B**) and not always distinct from the neck, and eyes with round pupils. These snakes have grooved fangs that are short, fixed, and covered by mucous membrane. In addition, their behavior is usually quite active, and most are oviparous (lay eggs).

Viperids have keeled scales (**Fig. 3**), a stocky build with a short tail, and due to the location of the venom glands, a triangle-shaped head distinct from the neck. The great majority have vertically elliptical or slit-shaped, pupils that can open wide to cover most of the eye or close almost completely, which helps them to see in a wide range of light levels. Their fangs are long, movable, and canalized like hypodermic needles. Typically, vipers are nocturnal and ambush their prey. There are two subfamilies, typical vipers (Viperidae) and pit vipers (Crotalinae).

Sea snakes (Hydrophilidae), an elapid often considered as a separate family, have adapted to a marine way of life in different ways and to various degrees. All have evolved paddle-like tails for swimming and the ability to excrete salt. Most also have laterally compressed bodies, their ventral scales are much reduced in size, their nostrils are located dorsally, and they give birth to live young (viviparity). This reduction in ventral scaling has greatly diminished their land mobility, but aids in swimming. All sea snakes are venomous.

Differentiating features of poisonous and non-poisonous snake: Snake can be differentiated on the basis of anatomy of head pupil fangs and tail. Venomous snake has triangular head, elliptical pupil, venom apparatus, and single row tail. Nonvenomous snake has rounded head and pupil, double row tail, and no venom apparatus. Differentiating features are shown in **Figure 4**.

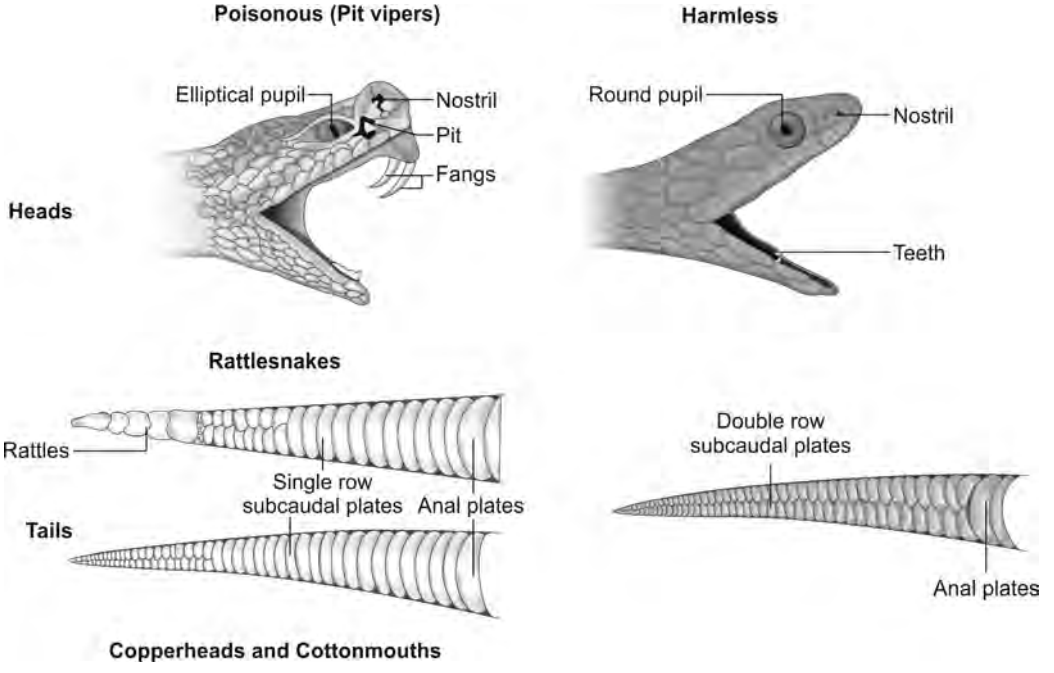

FIG. 4: Differentiating features of poisonous and nonpoisonous snake.

VENOM

Venom is mostly composed of proteins (96–98%) by weight, comprising both enzymatic and nonenzymatic ones, peptides, and glycoproteins. Venom composition is variable between the different species and also within the snake species from different geographical locations. The amount of venom also varies depending on how big the snake is, whether fed or not, season, age, sex, etc. About 80–90% of viperids and 25–70% of elapids, venom consists of enzymes of which 26 have been identified with 12 being common to most species. The enzyme/protein constituents (**Table 1**) of snake venom are described below.

TABLE 1: Components of snake venom.

Enzymes	*Nonenzymatic proteins*
Proteases—metalloproteinases and serine proteases	3-finger toxin
Phospholipases	Lectins
Nucleases (nucleotidases, DNAse, and RNAse)	CRISP (cysteine rich secretory proteins)
Arginine ester hydrolases	Cobra venom factors
Hyaluronidases	Nerve growth factor
L-amino oxidase	Natriuretic peptides
Acetylcholinesterases	Vascular endothelial growth factors (VEGFs)

Mechanism of Action-snake Venom

Krait and Russell's viper has presynaptic neurotoxin that means acetylcholine release is inhibited from the presynaptic membrane so recovery is slow and delayed and depends on regeneration of terminal axons. While cobra venom has postsynaptic neurotoxin that means cobra toxins bind to acetylcholine receptors and produce neuromuscular blockade. Anticholinesterases reverse the neuromuscular blockade thus neostigmine is useful in cobra but not in krait/viper.

CLINICAL FEATURES OF SNAKE ENVENOMATION

Signs of local toxicity at the bite site would suggest envenomation. Signs of systemic toxicity of viperid and elapid species are as listed in **Tables 2** and **3**.

MANAGEMENT OF VENOMOUS SNAKEBITE

The management of snakebite includes firstly ascertaining whether it was a snakebite at all, if yes as whether venomous or not as also looking for signs and symptoms suggestive of both local and systemic envenomation. Evidence of venomous snakebite per se does not establish envenomation as a good number of bites especially with Cobra species could be dry (bite without injection of venom). Onset of symptoms is variable and would depend on a number of factors including amount of venom injected, bite site, body mass, level of activity immediately after bite, use of pressure bandage, etc. Absorption tends to be

TABLE 2: Signs and symptoms suggestive of viperid bite (hematotoxic).

Clinical signs	*Symptoms (biochemical parameters suggesting envenomation)*
Presence of fang marks with significant local signs at the bite site such as swelling, pain, erythema, and cyanosis	Nausea, recurrent vomiting, and abdominal pain
Tender lymphadenopathy of the nodes draining the bite site	
Hemoptysis, epistaxis, hematuria, hematemesis and melena, chemosis, macular bleed, excessive menstrual bleed, bleeding from the bite site or cannula, bleeding into the muscles, gingival sulci bleed, bleeding into the skin, and mucous membranes showing as purpura or petechiae (Devaraj, 1979; Menon, 2014)	• Deranged hemostatic profile evidenced by either of or all of an abnormal • WBCT—whole blood clotting test • PT (prothrombin time) >1.5 times control • Activated plasma thromboplastin time (APTT), 1.5 times above normal
Abdominal tenderness	Low back ache or loin tenderness
Hypotension resulting from hypovolemia or direct vasodilatory effect of venom	Muscle pain indicating rhabdomyolysis
Lateralizing signs suggestive of an intracerebral bleed	• Low platelet count <100,000/cmm • Crenated RBC's in peripheral smear
Bilateral parotid enlargement (viper head appearance)	Rise in serum urea and creatinine, 30% over that of baseline
Conjunctival edema and subconjunctival hemorrhage	Proteinuria
Confusional state	Raised D dimer
Jaundice	Raised liver enzymes—AST and ALT
Ptosis (*Russell viper* bite)	Decreased fibrinogen
	Dysgeusia with a metallic taste in the mouth
	Passage of reddish or dark-colored urine or a reduction in the amount of urine

(AST: aspartate transaminase; ALT: alanine transaminase; RBC: red blood cell)

TABLE 3: Signs and symptoms suggestive of elapid bite—cobra and krait (neurotoxic).	
Clinical signs	***Symptoms biochemical parameters suggesting envenomation***
Fang marks, swelling, necrosis, blistering and local reaction at the bite site, and lymphangitis	Pain, swelling, and inflammation of the bitten part
Descending paralysis, initially of muscles innervated by cranial nerves, commencing as a ptosis, diplopia, or an ophthalmoplegia (the eyelid feels heavy with a difficulty in focusing)	Diplopia, dysphagia, dysgeusia (tingling sensation in the tongue with a loss of taste), dysphonia, and dyspnea (5D's)
"Broken neck" sign due to paralysis of neck muscles	Descending paralysis
Diaphoresis, circumoral pallor, and paresthesia	Abdominal pain and vomiting
Miosis (pupillary constriction)	Profound thirst
Painful lymphadenopathy	Palpitation, breathlessness, and chest pain
Paralysis of jaw and tongue may lead to upper airway obstruction and aspiration of pooled secretions as the victim is unable to swallow	Confusional state usually due to cerebral hypoxia
Bulbar paralysis and respiratory failure can cause cyanosis, altered sensorium, and coma	Fall in tidal volume/respiratory volumes
Krait bite often presents in the early morning with paralysis that can often be mistaken for a stroke	

more when bitten proximally as there is much less distance for venom to traverse to reach the central circulation as also when bitten in areas which are highly vascularized and with less of subcutaneous fat absorption tends to be rapid, e.g., scalp. Increased physical activity involving movement of the bitten limb tends to increase absorption of venom especially so in children with less of subcutaneous tissue and a low body mass. Lower blood volume in children leads to more concentration of venom in the circulation.

Brief History and Physical Examination

The questions to be asked are, time of bite and place where bitten (inside the house, near a water body, fields, plantation, etc.), activity at the time of bite, activity immediately after the bite and first aid given, previous bite or antisnake venom (ASV) administration, alcohol intake, and other diseases especially diabetes, hypertension, and cardiac or neurological conditions. A pictorial chart showing the common venomous snakes of the area is shown for identification. The fang marks are searched for and marked as also signs of inflammation including tender enlargement of the draining lymph nodes examined for and immediate first aid should be provided.

First Aid

Symptoms of anxiety related to snakebite may mimic some of the neurological symptoms and should be allayed. Sedatives should not be given as it would mask the symptoms of neurotoxicity in an elapid bite. Rings, wristwatch, bracelets, bangles, anklets, etc., on the bitten limb are removed and the bite site should be washed in cold water. Tight ligatures and tourniquets should not be applied as that can lead to gangrene of the affected limb and increased local reaction at the bite site. A pressure bandage is advocated similar to one which would be applied for immobilizing a limb in case of a fracture. The pressure bandage could be tied such as to be able to insinuate one finger between the bandage and limb. Venom is absorbed through the lymphatics (large molecular weight fractions) and small venules (small molecular weight fraction), pressure adequate to compress the lymphatics and venules would be enough to retard entry of venom into the central circulation.

In case of signs envenomation, the pressure bandage/tourniquet is to be only removed after the ASV has been started, preferably half an hour after starting ASV. Sudden release of venom on removal of a tourniquet has led to respiratory arrest in cases of elapid bites. Injection tetanus toxoid is given 0.5 mL IM irrespective of whether venomous or nonvenomous, for pain management oral paracetamol and tramadol are recommended but aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) are not recommended.

Triaging

Patient should be assessed immediately in triage. Airway assessment should be priority. Tracheal intubation and initiation of mechanical ventilation are helpful in patient with respiratory distress and bulbar palsy. Early critical care support is given for multiorgan failure to the patient and after resuscitation, antitetanus toxoid antibiotics are given for preventing wound sepsis.

Whole Blood Clotting Test

The victim is triaged by way of observation for ptosis to rule out neurotoxicity and signs of bleeding at any site. The most common bleed is observed in the gingival sulci. This is complemented by a WBCT (whole blood clotting test) (**Fig. 5**), which is considered the most reliable test of coagulation in hemotoxic bites which can be carried out at the bed side:

- *Procedure*: A 2–5 mL of fresh venous blood is placed in a new, clean, and dry glass test tube and left at ambient temperature for 20 minutes. It is important that the tube be clean glass and dry as the mechanism under review is the contact clotting mechanism. The use of plastic bottles, tubes, or syringes will give false readings and should not

be used. The glass vessel should be left undisturbed for 20 minutes and then gently tilted not shaken. If the blood is still liquid then the patient has uncoagulable blood. The test tube must not have been washed with detergents as this will inhibit the contact element of clotting mechanism. The test should be carried out every 30 minutes from admission for the first 3 hours. If everything is normal, it is repeated at 1 hour interval until 6 hours and twice more at 3 hours intervals and then at 6 hourly intervals till 24 hours.

- *Interpretation*: If all the tests are normal no further triage would be needed. A normal 20 WBCT and clot lysis would exclude a viperid envenomation. But it occasionally so happens that the bleeding parameters turn abnormal only 24 hours after the bite, especially in pit viper bites.

Differentiating Hematotoxic (Viperid) and Neurotoxic (Elapid) Bites

Hemostatic abnormalities are prima facie evidence of viperid bite given a history of snakebite. All viperid bites can potentially cause renal failure. Rarely ptosis can also be seen with viperid bites (*Daboia russelii*). Presence of signs and symptoms (***see*** **Table 2**) with hemostatic abnormalities as evidenced from an abnormal WBCT or a Prothrombin time and activated plasma thromboplastin time (PT/APTT) >1.5 times normal suggests viperid envenomation. Signs of neuroparalysis, typically starting with ptosis and proceeding on to a descending paralysis are suggestive of an elapid bite (***see*** **Table 3**). Muscles innervated by cranial nerves are involved first, descending downward.

Apart from the bleeding, clotting abnormalities, *Russell viper* envenomation (south India and Sri Lanka) can also present with dark brown-colored urine acute renal insufficiency, ptosis, ophthalmoplegia, and facial paralysis. While *Russell viper* (Myanmar) can produce conjunctival edema (chemosis), and acute pituitary insufficiency. Syndromic approach of snake bite is described in **Figure 6**.

Laboratory Investigations

Recommended laboratory test are described below:

- *Hematology*—total Leukocyte count, differential count, erythrocyte sedimentation rate (ESR), platelet count, and blood grouping. Blood grouping should be done immediately as venom fractions are known to interfere

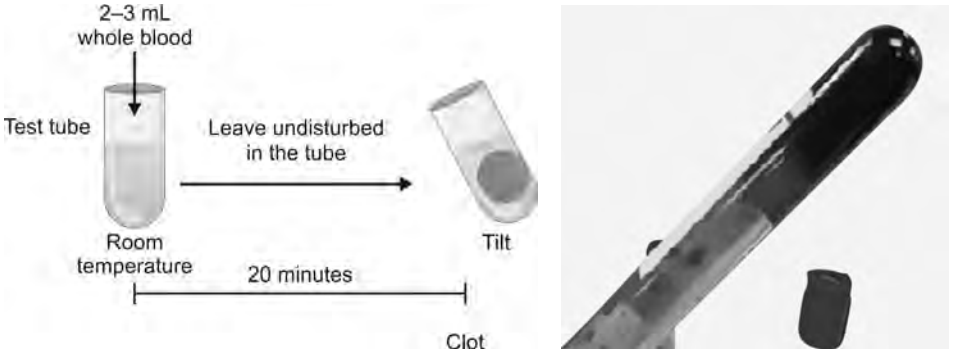

FIG. 5: Showing procedure of 20 whole blood clotting test (WBCT) to check coagulopathy in snake bite. ***(For color version, see plate 52)***

Syndrome 1	• Local swelling with bleeding and clotting abnormalities—all species of Viperidae • Local swelling with bleeding, clotting abnormalities with shock or acute kidney injury dark brown urine, facial paralysis, ptosis ophthalmoplegia—*Russel viper* (India and Sri Lanka) • With conjunctival edema (chemosis and acute pituitary insufficiency *(Russel viper Myanmar)*
Syndrome 2	• Local swelling with paralysis—*Cobra/King cobra* • Minimum or no local swelling with paralysis, bitten on ground while sleeping—*Krait*
Syndrome 3	• Bitten on land—*Russel viper* • Bitten on land while sleeping indoor—*Krait* • Bitten in water—*Sea Snake*

FIG. 6: Syndromic approach to snake bite.

with grouping test. Peripheral smear (to look for crenated RBCs, an early sign of envenomation) is done.
- Prothrombin time and activated plasma thromboplastin time, serum fibrinogen, and serum D dimer.
- *Biochemical*—aspartate transaminase/alanine transaminase/alkaline phosphatase (AST/ALT/ALP)/serum bilirubin.
- Urea/creatinine/Na^+, K^+, creatinine phosphokinase, and blood sugars.
- *Urinalysis*—urine routine and microscopy.
- Myoglobin/hemoglobin.
- Platelets, urinalysis, Hb, and blood urea nitrogen (BUN) to be repeated at 12 hourly intervals the first 2 days and daily in case of viperid bites.

SPECIFIC TREATMENT FOR SNAKE BITE

Antisnake Venom

The only treatment available for venomous snakebite is ASV. Types of ASV available are polyvalent-liquid/ dry lyophilized. Dose in victim is same in all age group, child, pregnancy, and elderly. Regarding ASV Anaphylaxis, there are no recommendations of test dose. Premedication with antihistamine (pheniramine 25 mg IV) and hydrocortisone (100 mg IV) can be given but no evidence that this regimen is effective in preventing the ASV reaction. Keep Injection adrenaline 0.5 mg 1:1,000 ready. Physician should be ready to handle this situation. Shelf life of liquid ASV—2 yearsat 4°C.

Indications of Antisnake Venom

If following features develop in patient with suspected or proven snake-bite—rapid developing swelling in more than half of the affected limb, enlarged and tender lymph node. Coagulation abnormalities are epistaxis, hemoptysis, hematuria, and gum bleeding. Neurotoxic features are ptosis, ophthalmoplegia, regurgitation, and nasal voice bulbar palsy. Cardiotoxic features are hypotension, shock, and arrhythmia. Acute kidney injury (AKI) (renal failure)—features of rhabdomyolysis hyperkalemia dark brown urine oliguria or anuria, raised urea creatinine.

Doses of Antisnake Venom

Start with 10 vials of ASV diluted in 100 mL of normal saline. Start ASV at 10–15 drops/min for the first 15 minutes, watch for allergic reactions. If there is no evidence of reaction to the ASV, continue with the ASV at a constant speed such as to finish in 1 hour. Continue to monitor the vital signs at 5 minutes intervals for the first 30 minutes and then at 15 minutes intervals for 2 hours.

Further Requirement of Doses

Repeat doses of ASV are given as 10 vials, 6 hours after the first dose in case of viperid bites as the liver takes up to 6 hours to replenish the coagulation factors. Doses >30 vials are rarely required, if symptoms do not settle with 20 vials other causes to be looked for like a species not covered by the polyvalent ASV, geographical variation of venom of the same species, etc. In cases of elapid bites, 10 vials of ASV could be repeated after 2 hours, if symptoms of neuroparalysis have not improved. Very rarely does one require doses of >20 vials in elapid bites. Mechanical ventilation would be required in patients with respiratory failure. Signs of recovery are spontaneous bleeding from various sites which usually stops, blood starts clotting (20 WBCT), urine color become normal, recovery in shock, and rise in blood pressure. Feature of postsynaptic neurotoxic (cobra bite) improves within hours but presynaptic neurotoxic feature (krait bite) takes longer time to improve.

Neostigmine and Cobra Envenomation

Cobra venom is alpha-bungarotoxin, which reversibly blocks postsynaptic acetylcholine receptors. Neostigmine is an anticholinesterase that prolongs the half-life of acetylcholine and can therefore reverse respiratory paralysis and neurotoxic symptoms. It is particularly effective for postsynaptic neurotoxins such as that of *Naja naja* venom. Despite the fact that the neostigmine test (neostigmine 0.5 mg IM with atropine 0.6 mg IV) was actually an Indian discovery, it is still poorly used in India. There is doubt over its efficacy against presynaptic neurotoxins such as those of the *Bungarus caeruleus* and the *Daboia russelii*.

In case of neuroparalysis, *neostigmine*—0.5—2.5 mg in adults and 0.025 mg/kg in children IV infused over 5 minutes. Give concurrent administration of atropine 0.6—1.2 mg IV in adults and 0.01 mg/kg of atropine IM or SC in children. If the neostigmine test is positive, same is repeated at half hourly intervals to a total of five doses. This is followed up by repeat injections at increasing intervals of 2–12 hours. If there is no improvement in symptoms after one hour, neostigmine should be stopped.

Observation for Antivenom Response

If an adequate dose of appropriate antivenom has been administered, the following responses may be observed:
- *General*: The patient feels better. Nausea, headache, and generalized aches and pains may disappear very quickly. This may be partly attributable to a placebo effect.
- *Spontaneous systemic bleeding (e.g., from the gums)*: This usually stops within 15–30 minutes.
- *Blood coagulability (as measured by 20WBCT)*: This is usually restored in 3–9 hours. Bleeding from new and partly healed wounds usually stops much sooner than this.
- *In shocked patients*: Blood pressure may increase within the first 30–60 minutes and arrhythmias such as sinus bradycardia may resolve.
- Neurotoxic envenoming of the postsynaptic type (cobra bites) may begin to improve as early as 30 minutes after antivenom, but usually takes several hours. Envenoming with presynaptic toxins (kraits and sea snakes) will not respond in this way.
- Active hemolysis and rhabdomyolysis may cease within a few hours and the urine returns to its normal color.

Supportive Care

In victims presenting with hematemesis, a Ryle's tube is passed into the stomach and in patients with a likelihood of progression to renal failure, it is prudent to have an indwelling Foley's catheter. Both this be done early in the course of hospitalization as the likelihood of traumatic bleed is considerable in case of viperid bites.

Pain Management

Nonsteroidal anti-inflammatory drugs are avoided in venomous snakebite especially viperid. Paracetamol could be given orally; in case of severe pain one could use tramadol hydrochloride.

Antibiotics

A wide range of antibiotics has been used as prophylaxis against secondary infection especially in cases of significant necrosis at the bite site. Combination of amoxicillin with clavulanic acid can be used for the same.

SPECIAL SITUATIONS

- *Late presentation of snake bite victims*: Sometimes snake bite patient presents late in emergency department after several days. ASV only neutralizes unbound venom so perform the 20WBCT test if coagulopathy presents then give 8–10 vials of ASV.
- *Children*: Children should receive the same dose as adults.
- *Pregnant women*: There is no dose modification and the same dose of ASV should be given as would be given to a nonpregnant lady. There is a significant likelihood of fetal loss in victims of snakebite treated with ASV. Envenomation is not an indication for a cesarean section in term pregnancy and the mode of delivery is decided on by the obstetric status. Lactating mothers can continue to breast feed their infants if their physical condition so allows.
- *Locked in syndrome*: Locked-in syndrome (LIS) is a condition in which a patient is aware but cannot move or communicate verbally due to complete paralysis of nearly all voluntary muscles in the body except for the eyes. Total LIS is a version of LIS wherein the eyes are paralyzed as well. This is not an uncommon presentation of elapid especially krait bite. It is mandatory that this diagnosis should be kept in mind in individuals presenting with flaccid quadriparesis without any other apparent cause. It has to be kept in mind that often the victim of a krait bite is unaware that he has been bitten and the local signs tend to be minimal.
- *Maximum dose of ASV*: There is no such maximum dose but doses above 30 vials do not benefit.
- *Use of fresh frozen plasma*: FFP or platelet concentrates in case of low platelet count or bleeding manifestation can be given.

COMPLICATIONS

- *Skin necrosis/amputations*—necrosis or debridement of the bitten part especially with a compartment syndrome. Rarely amputation of a toe, foot, or extremity.
- *Acute respiratory distress syndrome (ARDS)*—one of the most dreaded complications of venomous snakebite, especially viperids with a very high-mortality rate. Mechanisms postulated include direct action of venom fractions, aspiration and lung injury secondary to an inflammatory storm triggered by venom fractions. Mechanical ventilation is the treatment of choice with ancillary support.
- *Acute kidney injury*—a dreaded complications which can potentially be caused by all viperids. The causes of AKI in snakebite envenomation are multifactorial and include acute tubular necrosis (ATN), disseminated intravascular coagulation (DIC), hemoglobinuria, myoglobinuria, and direct nephrotoxicity of venom fractions being implicated. Pericapsular bleeding could also be causative. AKI is almost always reversible and is treated with renal replacement therapy following standard guidelines. Very unusually patients develop cortical necrosis in which case they proceed to develop chronic kidney injury (CKI). Typically patients who complain of flank pain within 12–24 hours of the bite are the ones who progress on to develop AKI.
- *Capillary leak syndrome (CLS)*: It is characterized by hypotension with hemoconcentration, hypoalbuminemia without albuminuria, and generalized edema. This syndrome is due to a capillary hyperpermeability with massive extravasation of plasma containing macromolecules <200 kD and at times up to 900 kD. This complication is also seen with viperid bites with a significant mortality. Zinc containing snake venom metalloproteinases has been implicated which act by degrading the compact proteins of basement membrane underlying the endothelial cells.
- *Cerebrovascular accident (CVA)*: Most venom fractions of both viperids and elapids do not cross the blood brain barrier. Other than for symptoms of neuroparalysis following an elapid bite, involvement of the CNS could be by way of a CVA secondary to either thrombosis or hemorrhage seen in viperid bites especially *Daboia Russelii* (*Russell viper*). Thrombotic CVA could be due to the direct thrombotic effect of viperid venom fractions or secondary to DIC. Thrombotic CVAs usually occur 2–3 days after the bite, whereas hemorrhagic CVAs generally occur earlier.
- *Cardiac complications* could range from myocarditis seen in elapid bites (cobra, sea snakes, etc.), hemopericardium in viperid bites, stress cardiomyopathy, acute coronary syndromes (ACS), and tachyarrhythmias. ACS is more seen in viperid bites, especially with *Russell viper*, thrombosis secondary to venom action or DIC being implicated just as with thrombotic CVA.
- *Hypopituitarism* one of the long-term complications reported with a viperid bite, especially *Russell viper* resulting from a Sheehan like syndrome secondary to bleeding in the pituitary fossa.
- *Eczema/squamous cell carcinoma*: Severe eczema at the bite site has been reported with snakebite envenomation. Very rarely squamous cell carcinoma has been reported at the bite site.
- *Psychological trauma*: There is a significant psychological trauma attributed to snakebite and hospitalization for the same especially in children and in women.

DISPOSITION

Snake bite patient should be admitted in intensive care unit because they may require management for various complications such as respiratory failure, and acute renal failure due to rhabdomyolysis needs hemodialysis, intracranial bleed, DIC, encephalopathy, paralysis and coma, hypotension and shock, tetanus and cellulitis, and compartment syndrome and gangrene.

SUMMARY

Venomous snakebite is a medical condition with a far-reaching impact on the family of the victim. Snakebite which has been relisted as a NTD (neglected tropical disease) is a common disease condition that one encounters anywhere in the tropics and is eminently amenable to treatment. If diagnosed early and treated well the victim goes back to a normal productive life which cannot be said of most of the other catastrophic diseases that one encounters during daily practice.

246 CHAPTER

Arthropodes: Insect Bites and Stings

Au Kin Heng Constantine

INTRODUCTION

An arthropod is an invertebrate animal with a segmented body and paired, is jointed appendages and an exoskeleton. The name *arthropod* is based on the Greek *arthr*, meaning joint, and *pod*, meaning foot. Arthropods comprise 84% of all animal species on Earth. Entomologists classify arthropods into classes, orders, families, genera, and species. Common orders include Blattaria (cockroaches), Coleoptera (beetles), Diptera (flies and mosquitos), Ephemeroptera (mayflies), Hemiptera (wasps, ants, and bees), Isoptera (termites), Lepidoptera (butterflies and moths), Odonata (dragonflies and damselflies), Orthoptera (grasshoppers and crickets), Phthiraptera (lice), and Siphonaptera (fleas). As healthcare professionals, it is often not necessary be aware of this detailed classification. A description of the morphology of arthropods may be good enough for clinical practice. The following are some arthropods that have medical significance. Adult insects consist of six legs and three body regions (head, thorax, and abdomen), and some insects have wings. Adult spiders have eight legs and two body regions (cephalothorax and abdomen). Adult mites and adult ticks have eight legs and one body region but no true mouth (with mouthparts only). Adult scorpions have eight legs with a broad flat body region and a tail with a stinger. Adult centipedes have a pair of legs in each body segment. The number of body segments is numerous and the shape is usually flat. Adult millipedes have two pairs of legs in each body segment and the number of body segments is numerous and the shape is usually cylindrical. Because millions of arthropod species exist on Earth, this chapter can only include common ones that have medical significance. Stress is put on the general principles. Travel has become very popular and many exotic regions have become accessible. In managing a patient who has a recent travel history, clinicians should think about the possibility of arthropod-related diseases of the destinations. Delusion of parasitosis and other psychiatric diagnoses like amphetamine bugs must be excluded.

Etiology

Because millions if not billions of different arthropod species exist on Earth (**Fig. 1**), the following discussion only includes those ones that people commonly encounter. Adult arthropods may look very different from larval/developmental stages. Please consult a biologist, entomologist, veterinary surgeon, or poison center if needed.

PATHOPHYSIOLOGY

Exposure to arthropods can be experienced via bites, stings, local irritation causing local infection, systemic hypersensitivity, anemia, ingestion, and arthropod-borne diseases and ingestion. Venom and irritating chemicals complicate the condition. The proceeding section is a brief summary of the common contacts (**Table 1**).

Locally

- *Blockages of orifices and skin attachment*: Small arthropods may enter and block any orifices of our body. Sometimes arthropod body parts remain lodged. A tick may stick strongly on the skin.
- *Local wounds*: Bites, stings, and even scratching by arthropod feet might result in local wounds. The wounds are usually small. Some wounds may carry foreign bodies. Bees leave their stings behind. Mouthparts may be broken. Soil or other dirt may be present. Local inflammation with increased blood flow, increased capillary permeability, and increased white cell count are common. The severity of a rash can range from local pain, itchiness, and swelling that lasts for a few hours to extensive swelling that lasts for days. As with every wound, local infection by superimposed bacteria can happen. Cellulitis, necrosis, and sepsis may follow.
- *Invasion of human tissues—myiasis*: Myiasis means infestation of larvae of flies in the organs or tissues of humans or other animals. Myiasis can be classified into intentional therapeutic myiasis, accidental myiasis, facultative myiasis, and obligate myiasis. Therapeutic myiasis is to use larvae for wound debridement. The use was very common before the antibiotics era. Accidental myiasis occurs when eggs are ingested accidentally. The larvae may survive for a short while, which is considered a relatively benign condition. The patient may complain of stomach pain, nausea, and vomiting, which is also known as pseudomyiasis because of the lack of full development of a fly. In facultative

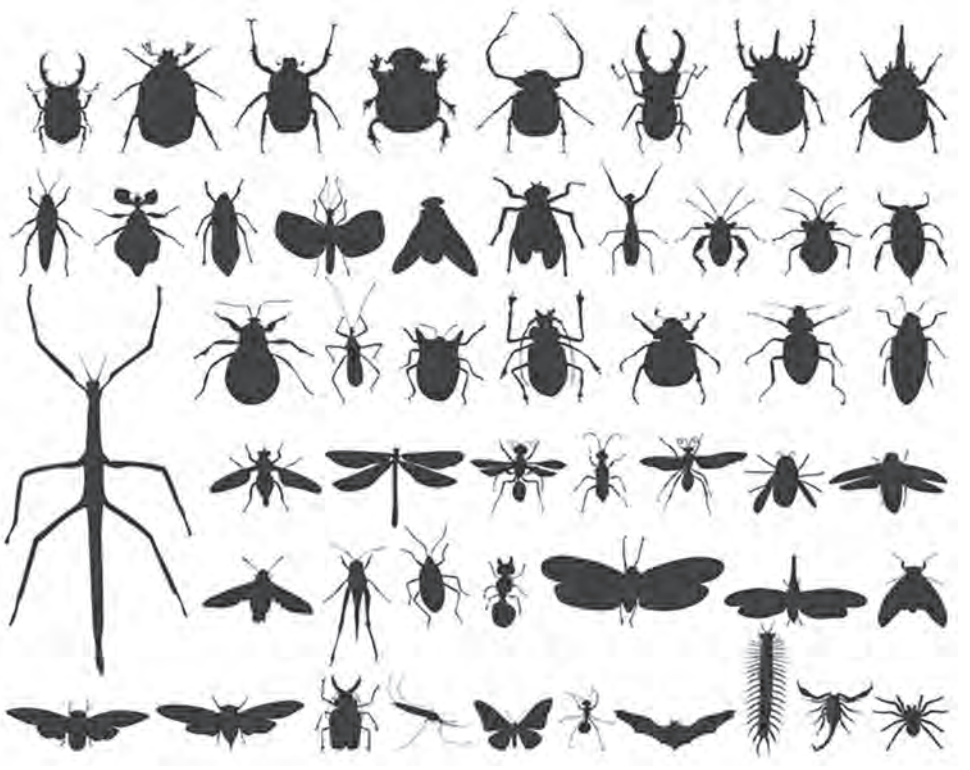

FIG. 1: Different types of arthropod.

TABLE 1: Common arthropods that have contact with humans.

Arthropod	*Nature of contact/Wounds and harm*	*Transmission of diseases*	*Remark*
Ants			
Ants (worldwide)	• Bite and sting • Skin lesion is erythematous with a central wheal. Later, pustules may develop	Not known	
Fire ants (worldwide), harvester ants (USA), and velvet ants (USA)	• Painful sting • Skin lesion is erythematous with a central wheal. Later, pustules may develop • Reexposure can lead to serious systemic reactions	Not known	
Bees			
Bees (worldwide)	• Sting • The wound shows local swelling with a central white spot with erythematous halos • Reexposure can lead to serious systemic reactions	Not known	
Honey bees (worldwide), bumble bees (worldwide), and Africanized honey bees (in Central and South America, Mexico, and USA)	• Painful stings • The wound shows local swelling with a central white spot with erythematous halos • Reexposure can lead to serious systemic reactions	Not known	
Beetles			
Beetles (worldwide)	• Most are benign (except blister beetles)	Not known	
Blister beetles (worldwide)	• Secrete irritating chemicals causing kidney failure, cardiovascular collapse, coma, and even death	Not known	Cantharidin penetrates the skin and pederin causes blisters

Continued

Continued

Arthropod	*Nature of contact/Wounds and harm*	*Transmission of diseases*	*Remark*
Bugs			
Bed bugs (worldwide)	• Bite and suck blood from humans • Red blotches grouped in linear pattern with urticarial wheals and sometimes bullous	Suspected	
Conenose bugs (in the Americas)	• Bite at night • Feed on human blood • Variable lesions	Vectors for *Trypanosoma cruzi* that causes Chagas disease via fecal contamination of the bite	
Wheel bugs (USA)	• Painful bite • Lesion shows swelling, inflammation, and induration	Not known	
Caterpillars			
Urticating caterpillars (worldwide)	• Venomous hairs or spines that can sting or irritate the skin with immediate burning sensation • Variable lesions • Burning sensation	Not known	The venom of *Lonomia* in South America contains anticoagulants
Centipedes			
Centipedes (worldwide)	• Painful bite • Typical lesions show two hemorrhagic punctures	Not known	Cytolysin-based venom
Cockroaches			
Cockroaches (worldwide)	• Food contamination and possibly allergy • Bite occasionally • Blocking orifices	Many bacteria, fungi or viruses mechanically	
Earwigs			
Earwigs (worldwide)	• Relatively harmless • Abdominal cerci of larger ones may pinch human skin • Trivial lesion	Not known	Some live in water wells
Fleas			
Adult fleas (worldwide)	• Bite and feed on blood • The lesions vary from one species to another	• Plague (*Yersinia pestis*), rickettsial diseases (murine typhus, *Rickettsia typhi*) • An intermediate host of dog tapeworm (*Dipylidium caninum*)	
Flies (biting)			
Black flies (worldwide)	• The lesion has variable patterns with systemic reactions	Onchocerciasis	
Congo floor maggot (sub-Sahara Africa and Cape Verde Islands)	• Myiasis • Nocturnal bite blood-feeding larvae • The lesion is usually a pinprick	Not known	
Deer flies (worldwide)	• Painful bites • The lesion is deep and singular; cellulitis	Tularemia (deer fly fever/rabbit fever) and loiasis (Loa Loa)	
Horse flies (worldwide)	• Painful bites • The lesion is deep and singular; cellulitis	Not known	
Biting midges (worldwide)	• Bite • The lesion is minute popular in pattern with erythematous halo • Wheals may occur	Oropouche fever (a virus in the Simbu group of *Bunyaviridae*)	

Continued

Continued

Arthropod	*Nature of contact/Wounds and harm*	*Transmission of diseases*	*Remark*
Sand flies (worldwide)	• Bite and suck blood • Lesions may be red papules or wheals	Leishmaniasis (*Leishmania donovani*), bartonellosis (*Bartonella bacilliformis*), and sandfly fever	
Stable flies (worldwide)	• Bites • The lesions are small evanescent vesicles	Not known	
Tsetse flies (tropical Africa)	• Bites • The lesions are small punctures with hemorrhaging	African trypanosomiasis (*Trypanosoma brucei*)	
Flies (nonbiting)			
House flies/filth flies (worldwide)	Do not bite. They may contaminate food and water and may cause myiasis	Transmission of disease is mainly carried out mechanically. More serious examples include typhoid, cholera, and dysentery	
Eye gnats (almost worldwide)	Do not bite but may scratch the eyes	Yaws (*Treponema pertenue*) and pinkeye are transmitted by eye gnats	
Nonbiting midges (worldwide)	Hypersensitivity reactions in the eyes or respiratory tract	Not known	Mass emergence of nonbiting midges may cause traffic accident and other nuisances
Flies (nonbiting) and myiasis			
Human bot flies (Central and South America and Mexico)	• Do not bite but may cause myiasis • Superficial, painful, swollen with a central opening	Not known	
The larvae of screwworm flies (Central and South America, South Pacific region, and tropical Africa)	• Extensive damage to human tissues and cause pocket-like sinuses • Fatal myiasis	Not known	
Tumbu flies (tropical Africa)	• Red or shiny nodules and furuncular myiasis	Not known	
Wohlfahrtia flies consist of *W. magnifica* (Arabian Peninsula, Asia, North Africa and southern Europe)	• Myiasis • Causes deep lesions	Not known	
W. vigil (Canada and northern USA)	• Myiasis • Causes papules or pustules	Not known	
Lice			
Body lice (worldwide)	• Bites and feeds on human blood • The lesion is red papules, 3–4 mm in diameter, with purpuric halo	Epidemic typhus (*Rickettsia prowazekii*), trench fever (*Bartonella quintana*), and louse-born relapsing fever (*Borrelia recurrentis*)	Not the bite but crushing the lice and their feces into skin transmits these diseases
Head lice (worldwide)	• Irritate the skin and may cause secondary infection • Itchy scalp is the common presentation	Not known	
Pubic lice (worldwide)	• Irritates the skin and may cause secondary infection • The lesion is variable and may present as blue spots	Not known	
Millipedes (worldwide)	• May burn the skin • The lesions range from yellow to brown. Blisters may be present	Not known	

Continued

Continued

Arthropod	*Nature of contact/Wounds and harm*	*Transmission of diseases*	*Remark*
Mites			
Chigger mite (worldwide)	• Irritation and itchiness on the skin • The lesion is variable and may present as a red, dome-shaped papule	Scrub typhus in Asia	
House dust mites (worldwide)	• Do not bite but cause allergies, especially in the respiratory tract	Not known	
Biting mites (worldwide)	• Painful bites • The lesions vary	May possibly transmit rickttesial pox	
Scabies mites (worldwide)	• Intense itchiness and secondary infection • Burrows and papules are formed on the skin	Not known	
Follicle mites (worldwide)	• Live on human skin and are usually harmless	Not known	
Mosquitoes (worldwide)			
Mosquitoes (worldwide)	Bite and cause puncture, hemorrhages, popular lesions, or wheals with edema	Malaria (*Plasmodium vivax, Plasmodium ovale, Plasmodium malariae,* and *Plasmodium falciparum*), yellow fever (flavivirus), dengue fever (DEN-1, DEN-2, DEN-3, and DEN-4), Rift Valley fever, Ross River virus disease, and Chikungunya fever. Mosquitoes transmit lymphatic filariasis (*Brugia malayi*), and many other filarial worms. Encephalitis transmitted by mosquitoes include Eastern equine encephalomyelitis, Western equine encephalitis, Venezuelan equine encephalitis, Japanese encephalitis, St. Louis encephalitis, West Nile encephalitis (West Nile virus), and La Crosse encephalitis	
Moths			
Moths (worldwide)	• Stinging hairs or spines cause skin irritation • Some body parts may detach and cause irritation in the respiratory system • Skin lesions vary	Not known	
Pentastomes/Tongue worms			
Pentastomes/tongue worms (worldwide)	• Reside in human liver, spleen, lungs, throat, and eustachian tubes • They are benign and may cause irritation in the throat	Not known	
Scorpions			
Scorpions (worldwide)	Sting painfully and some species give fatal venomous sting to humans. Lesions vary	Not known	
Spiders			
Violin spider (Africa, Australia, South America and USA)	Bites cause variable lesions plus necrotic wounds and possible hemolytic anemia	Not known	

Continued

Continued

Arthropod	*Nature of contact/Wounds and harm*	*Transmission of diseases*	*Remark*
Widow spiders (worldwide)	• Bite causes two small puncture wounds, and neurotoxic venom may be fatal • Myocarditis and dyspnea can occur as well	Not known	
Hobo spiders (Europe and USA)	• Bite is usually painless at first. Induration followed by expanding erythema and blister • Necrosis may develop with eschar formation	Not known	
Sydney funnel web spiders (Australia)	• Bite site may be extremely painful • Death within 1 h	Not known	The venom acts on the somatic and autonomic nerves, quickly causing hypotension and apnea
Tarantula spiders (USA)	Painful bites. The urticating hair may cause much irritation on the skin and mucosal surfaces	Not known	
Ticks			
Ticks (worldwide)	• Bite and feed on human blood. The lesion is a red papule with erythema. Hypersensitivity to tick saliva causes erythematous ring • Tick-paralysis is caused by the neurotoxin in tick saliva	Babesiosis (protozoan; Europe and USA), Colorado tick fever (virus; Canada and USA), Crimean-Congo hemorrhagic fever (virus; Africa, Asia and Europe), Kyasanur Forest disease (virus; India), Lyme disease (spirochetes; Australia, China, Europe, Japan, and USA), relapsing fever (spirochetes worldwide), *Rickettsiae* (many diseases, e.g., African tick bite fever in sub-Saharan Africa; American boutonneuse fever/maculatum fever in the Americas; boutonneuse fever/ Mediterranean fever in Africa; ehrlichiosis and anaplasmosis in the USA; Japanese spotted fever in East Asia, Japan, Mediterranean, and the Middle East; North Asian tick typhus/Siberian tick typhus in Central Asia, Mongolia, and Siberia; Queensland tick typhus in Australia; Rocky Mountain spotted fever in the western hemisphere; tickborne lymphadenopathy in Europe), tick-borne encephalitis (virus in Europe), and tularemia (bacterium in Canada, Europe, Japan, Mexico, Russia, USA)	
Wasps			
Yellow jackets (worldwide), hornets (worldwide), and paper wasps (worldwide)	• Give painful stings and may cause allergic reactions • The lesion is central white spot with erythematous halo • The degree of local swelling varies • Reexposure can lead to serious systemic reactions	Not known	

myiasis, a larva leaves the necrotic tissue and invades the healthy tissue, causing pain and damage. Screwworm flies and human bot flies may develop in human tissue. Tissue damage and occasional death may occur.

Systemic

Allergic reaction or hypersensitivity: Allergic reaction or hypersensitivity is usually classified into type I (IgE-mediated), type II (cytotoxic reaction), type III (antibody-antigen complex), and type IV (T-lymphocytes and macrophages). Type I, II, and III are usually immediate in onset, whereas type IV usually has a delayed onset of a few hours to days. The venom, protein substances, and foreign bodies infiltrated by stings and bites can certainly cause allergic reaction. Beware that a simple contact by an arthropod on the skin or mucous area can cause allergy. Local allergic reaction is usually irritating and may subside in a few hours. However, if the site involved is the throat or head and neck region, a severe local reaction can compromise the airway. Severe systemic allergic reaction can occur, if the allergens reach the blood or lymphatic circulation and different organs are involved. Anaphylaxis is one of the worst forms of systemic presentation of hypersensitivity. It is usually quick in onset, with obstruction in the upper airway and the lower airway. Swelling in the lips and tongue, dyspnea, and wheezing may be found. Pruritus, urticaria, erythema, and angioedema are found on the skin. Cardiovascular collapse may occur due to peripheral vasodilation, increased vascular permeability, and possibly arrhythmia.

- *Anemia*: Anemia, ranging from mild to severe, may occur depending on the number of bites and duration of bites.
- *Ingestion and food contamination*: For some readers, eating arthropods may be an alien idea. However, people do eat arthropods. For example, scorpions are roasted or cooked in other ways in China. It is believed that the venom of scorpions is heat liable. Some may consume scorpions raw with the tail and stinger removed. If the preparation is not perfect, the venom may enter the body via the gastrointestinal tract. Gastric acid and other enzymes may denature the venom though. Some players of survival games eat scorpions and black widow spiders. Ingestion of the arthropods, their body parts, or chemicals may be accidental as well. Cockroaches, flies, and other arthropods may contaminate food by their body parts, fluids, feces, etc.

Venom and other Irritating Chemicals

Arthropods have many venoms and irritating chemicals. Here are some common examples.

- *Necrotic venom*: The venom in bees and wasps has phospholipase A. The venom in violin spiders has lipase and hyaluronidase. Possibly, the lipase induces neutrophil chemotaxis, causing tissue necrosis.
- *Neurotoxic venom*: Tick paralysis is caused by a neurotoxin and the presentation resembles Guillain-Barré syndrome. The venom in widow spiders is a kind of neuromuscular-damaging protein. It affects ion transport, leading to sweating, muscular spasm, weakness, paralysis, and convulsions. Scorpion venom contains multiple low-molecular-weight proteins, salts, mucus, and some other organic compounds. The low-molecular-weight proteins increase the permeability of the sodium channel in the neuromuscular junction and the autonomic nervous system. Presentation includes blurred vision, paralysis, abnormal eye movement, excessive salivation, convulsion, respiratory paralysis, myocarditis, and death.
- *Other venoms*: In the bites of blister beetles, cantharidin penetrates the skin and pederin causes the blisters. *Lonomia* (a caterpillar in South America) venom contains anticoagulants and may cause severe bleeding. Centipedes bite with a cytolysin-based venom
- *Respiratory tract reaction*: House dust mites cause allergic reaction presented as asthma-like attacks. Other arthropods can cause allergic reaction in the respiratory tract as well.

CLINICAL PRESENTATION

- *Local*: In terms of skin or scalp presentation, arthropod contact ranges from no obvious sign to mild rash, papules, nodules, and necrotic tissue. The patient may have minimal complaints like light itchiness, light pain to severe itchiness, and pain.
- *Systemic*: Anaphylaxis, fever, sepsis, anemia, weight loss, and other signs may be present. Alternation in consciousness, coma, and even death, they may be caused by the contact alone or by the diseases transmitted.
- *Concerning features (red flags)*: More signs and more diseases may be present on top of the wound or rash after arthropod contact. Patients may not recall any bites, stings, or contact with an arthropod. Skin signs or wounds may not be obvious even for a poisonous widow spider. Clinicians are encouraged to seek more information about the arthropods that resided in their regions of practice. A patient may correctly recall an overseas trip, but details of a local trip may not be recalled as vividly. Offer hints like any contacts with wild or domestic animals, any local parks, woods, etc. For any patients with fever of unknown origin, unaccounted symptoms or signs, exposure to arthropods must be excluded. Warn a patient about delayed hypersensitivity, which may have an onset in terms of days. A skin rash, wound, nodule, ulcer, etc., with a history of arthropod contact can be caused by other diseases. Exclude allergic reaction against an antigen other than an arthropod. Exclude melanoma, basal cell cancer, and squamous cell cancer. Think of other causes of anemia. Sometimes tests for allergens and biopsy may be needed. Psychiatric illness, substance abuse, and withdrawal should be excluded.

EVALUATION

- *History*: Bites are common in many regions, especially in tropical and subtropical areas, but a patient may not be aware. Ask for any possibility of arthropod contact. If there was an arthropod contact, ask what, where, when, and how the contact was. Check the arthropod, identity the body shape, wings, number of legs, mouth parts, stingers, etc. Adult arthropods may look very different from larval/developmental stages. **Figure 1** may help in identification. Characteristics of the place like plants may help. Travel history must be checked. In addition to overseas travel, a hiking trip in the neighborhood may result in arthropod contacts. Ask for details of the trip such as the location, water source, and plants. Check the photos taken during the trip may give some hints. Change in occupation,

residence, hobbies, or recent cleaning of lodgings may give rise to arthropod contact. Ask for similar presentation in family members and friends because they may share the same exposure.

- *Physical examination*: Do not take arthropod bites or contact lightly. More signs and more diseases may be present on top of the wound or rash.
  - Beware of life-threatening signs, either present or in progression. Look for signs of severe allergic reaction like difficulty in breathing and hypotension.
  - Do not focus only on the wound. Do a general examination. In the general examination, look for pallor, jaundice, edema, lymph nodes, and splenomegaly. Look for signs of possible diseases transmitted. Check for fever. A simple contact does not usually cause fever.
  - Check the wounds. Note the severity of swelling and the location. A swelling in the head, neck, and throat regions demands special care.
  - The pattern and distribution of the rash, if any, may give a hint of the culprit.
- *Interpretation of finding*: It is important to grade the result of the contact. Do not miss any life-threatening conditions. Think about the possibility of transmitted diseases. Think of the differential diagnosis. A skin rash, wound, nodule, ulcer, etc., with a history of arthropod contact can be caused by other diseases, even malignant ones. Psychiatric illness, substance abuse, and withdrawal should be excluded.
- *Investigations*: Most arthropod-related cases do not need any investigation. For those severe cases, use the white blood cell (WBC), blood film (e.g., malaria and other parasites), and viral titer, e.g., dengue virus (usually two titers are needed to see the trend). For patients with possible organ failure, check the renal function and liver function. For suspected myocarditis, arrange cardiac enzymes and echocardiogram. A skin rash, wound, nodule, ulcer, etc., with a history of arthropod contact can be caused by other diseases. Exclude melanoma, basal cell cancer, and squamous cell cancer. Think of other causes of anemia. Sometimes tests for allergens and biopsy may be needed.

TREATMENT

Treatment includes prevention of bites, prevention of arthropod-borne infection, local wound care, supportive care, allergy (mild to severe), and antivenom. As in every aspect of medicine, prevention plays an important role. Avoid contact with arthropods.

Prevention

- *Personal protection*: Avoid using perfume in the wild because perfume may attract arthropods. Similarly, sweat may attract arthropods. Avoid contact with ants because they may be fire ants. Do not go near bee hives. Avoid contact with wild animals. For domestic animals such as pet dogs, use tick and flea collars or other products to repel ticks and fleas. Regular washing with antiarthropod shampoo helps to remove fleas and ticks. For other domestic animals such as horses, seek advice from veterinary surgeons for prevention of arthropods. Do not handle any sick or dead animals, even pets, unprotected. Always wear gloves, etc. For bedbugs, professional pest control may be needed. Wear long sleeves, long pants, etc., to protect the skin. Proper use of repellents such as DEET (N, N-diethyl-meta-toluamide) or the use of insecticides in the garden may help. Beware of allergies caused by repellents and insecticides. Beware that many commercial insect repellents or folk remedies may not work. Arthropods may hide in shoes, socks, pockets of shirts, blankets, bed linens, etc. Flip and check before use.
- *The environment*: General hygiene and proper handling of food and wastage can reduce the chance of survival of cockroaches, flies, and other arthropods. The mosquito *Aedes aegypti* can spread dengue fever, yellow fever, Zika virus, and chikungunya. Avoid stagnant water so that its eggs cannot develop properly. *Aedes aegypti* is most active just after sunrise and just before sunset but can bite at night. Anopheles mosquitoes, the vector for malaria, are active at dusk or dawn and active at night. Plan the activities accordingly. Mosquito nets, window screens, and bed nets can reduce the chance of mosquito contact. Dust mites can be prevented by regular and proper mattress cleaning. Furniture can be treated with both heat and steam. Isolation, either of a patient or others, is needed for scabies and hair lice until treated.
- *Vaccines and prophylaxis*: A vaccine is available for yellow fever. Prophylaxis against malaria is also available. Advice from a travel clinic will be useful. Make sure to receive a consultation as early as possible. Some vaccines or prophylaxes need repeated doses. For yellow fever, usually only government agencies have the drugs and appointments may be tight.
- *Food storage and preparation*: Food, raw or cooked, should be stored properly to prevent contamination by arthropods. Food must be properly cooked before consumption.

After Exposure

- *Do not crush the arthropod*: Crushing a mosquito while it is biting on the skin may be a second reflex for many people. Crushing a mosquito is relatively safe. For some arthropods, it may not be that safe. Epidemic typhus (*Rickettsia prowazekii*), trench fever (*Bartonella quintana*), and louse-born relapsing fever (*Borrelia recurrentis*) are transmitted by crushing the lice and their feces on the skin. Crushing also destroys the identity of the arthropod. Take a photo of the culprit if safe. Take note of the number of legs, color, shape, etc., of the arthropod.
- *Local wound*: The usual wound care must be conducted. Check for foreign bodies. Look for unusual swelling, necrosis, or sign of infection. In terms of treatment of local wounds, think of AI's: antihistamine, analgesics, antibiotics, antitetanus, [adrenaline/epinephrine (for anaphylaxis)], ice, and steroid. The possible route of administration can be topical, oral, intramuscular, subcutaneous, and intravenous. Local antihistamine cream may work for simple itchiness. Oral analgesics are usually good enough. Consider local antibiotics cream. Oral or even IV antibiotics may be needed for infected wounds. Because bites or stings may carry soil, the antitetanus status of the patients should be checked. Adrenaline is included here so as to stress the importance to exclude anaphylaxis. Steroid cream may be needed for severe itchiness. Beware of the adverse effects of treatment especially for ice and steroid.
- *Blockage of orifice*: If an arthropod blocks an orifice, removal must be done carefully. Light may sometimes

guide an arthropod to exit an orifice. Olive oil may float an arthropod out of the orifice. Removal of embedded arthropods such as maggots must be planned carefully. Breakage of the maggots may lead to hypersensitivity. Consult a clinical microbiologist, entomologist, a poison center, or a veterinary surgeon for the necessary precaution and prophylaxis before removal.

- *Remaining stings and ticks*: Removal of a remaining sting must be done carefully so as not to squeeze remaining toxin and chemicals into the skin. Consider using a card to scrub the sting out. Ticks can be removed with forceps or a tweezers with gentle traction. Consult experts if in doubt.
- *Systemic*: Look for signs and symptoms of allergic reaction. Antihistamine local or oral is usually enough for mild reaction. Add steroid if needed but with caution. IV antihistamine (e.g., diphenhydramine 1 mg/kg) and IV steroid are necessary for moderate reaction. Adrenaline, subcutaneous (SC), intramuscular (IM), or Intravenous (IV) is needed for severe life-threatening reaction. Some patients carry an EpiPen with them. In the prehospital setting, these patients may need help in the administration of EpiPens. Ventolin puff can relieve bronchospasm. Support the airway, breathing, and circulation with oxygen supply, intubation, IV fluid, and inotropes as the conditions require. Anaphylaxis means Intensive Care Unit (ICU) care. Always think of delayed hypersensitivity. If in doubt or because of a relatively high number of bites or stings, admit the patient for observation.
- *Specific treatment*: Permethrin can kill *Sarcoptes scabiei* (scabies) and lice. Other treatments are also available. Isolation, conduct contact tracing, and treat all the contacts. Careful surgical exploration and removal may be needed in some types of myiasis. Bursting of the maggots must be avoided. Infested tissues may be cleansed with nitrofurazone. Antivenoms exist for certain bites and stings (e.g., for certain species in scorpions and black widow spiders). Please contact a local poison center for advice. Professional pest control may be needed for certain arthropods. Please refer to the relevant chapters of this book for the treatment of the diseases transmitted. Please consult a microbiologist, entomologist, veterinary surgeon, or poison center if needed.
- *Follow-up*: For most bites, follow-up is not necessary. Arrange follow-up, if there is any worry about wound infection. Check for similar contacts with family members or colleagues. Arrange treatment if needed.

SCORPION STING

Scorpions are easily recognized, have 8 legs, have venomous stings, and there are 25 species, which can prove to be fatal to humans. Scorpions are widely distributed worldwide. Toxic varieties of scorpion are found in Middle East, India Mexico, South America, and Trinidad. There are 2,000 species of scorpions only about 25–40% are lethal. India is home to the most toxic and dangerous, lethal species of scorpion. Indian red scorpion (*Hottentotta tumulus*) is also known as eastern Indian scorpion of family Buthidae, which is found in India, eastern Pakistan lowlands of Nepal, and Sri Lanka.

They sting when stepped upon or threatened, fatality rate is 8–40%, are not aggressive. Its children who are mostly the victims as at times they may be barefoot. Its venom delays closing of neuronal sodium channels which results in autonomic storm, as there is sudden pouring of catecholamines into the circulation. Autonomic storm is seen by transient, parasympathetic, and prolonged sympathetic stimulation. Venom produces local as well as systemic manifestations. Local reactions my lead to itching, edema, ecchymosis with severe burning, pain, cardiac manifestation, with giddiness, bradycardia, hypovolemia restlessness, tachycardia, and pulmonary edema. Myocardial damage, caused by scorpion venom is due to pathogenic mechanism. Release of vasoactive inflammatory peptides and amine constituents (histamine, serotonin, bradykinin, leukotrienes, and thromboxane) induces coronary artery vasospasm and causes aggregation and thrombosis. Cardiotoxic effect of this scorpion venom causes myocarditis causes reduction of sodium-K ATPase, by releasing adrenaline, noradrenaline from neurons, ganglia, and adrenals causing increase in myocardial oxygen demand by direct inotropic and chronotropic effect on already compromised blood supply.

Scorpion venom also causes anaphylaxis by releasing allergic proteins, leading to anaphylactic shock in some victims of scorpion sting. Scorpion venom inhibits angiotensin, converting enzyme which results in accumulation of bradykinin, which ultimately leads to pulmonary edema. Cardiovascular system and pulmonary system are affected, which lead to death from pulmonary edema. Antivenom shows little effectiveness, however, mortality is reduced to <4% if prazosin is used in blood pressure. Scorpion venom is a water soluble, antigenic complex mixture of neurotoxin, cardiotoxin, nephrotoxin, hemolysin, phosphodiesterase, hyaluronidase, histamine, and other. Scorpion venom is used as immunosuppressants for various autoimmune disorders, such as rheumatoid arthritis, multiple sclerosis, also is used as an antimalarial.

Clinical Feature

Scorpion venom causes excessive depolarization due to opening of neuronal sodium channel. Symptom ranging from severe pain at the side of sting to vomiting breathlessness, sweating jerking movement of the extremities, and tachycardia with severe agitation. Symptoms can continue till 24–48 hours. Pulmonary edema, cardiac dysfunction, bleeding disorder, DIC, and pancreatitis are seen in sting from the lethal variety of scorpion from Asian and African countries.

Diagnosis

Tap test: Physician will tap at the site of the sting to see if pain gets severe, reaction is the indicator of a scorpion sting. There is over stimulation of sympathetic, parasympathetic, and central nervous system stimulation due the venom effect, hence after an hour of the scorpion sting, there is increase in blood pressure, heart rate tachyarrhythmias may develop. Elderly and pediatric patients are at special risk. "Roving eye" movement is common in children, along with twitching and muscle fasciculation weakness, agitation and opisthotonos, severe ataxia, and respiratory distress are also seen though less common.

Treatment

Wash the sting with soap and water, remove any jewelry example ring from finger if sting on finger. Apply cool compress 10 minutes on and 10 minutes off at the place of sting. Analgesics acetaminophen, tetanus prophylaxis to be given, benzodiazepines and opioids to be given for muscle

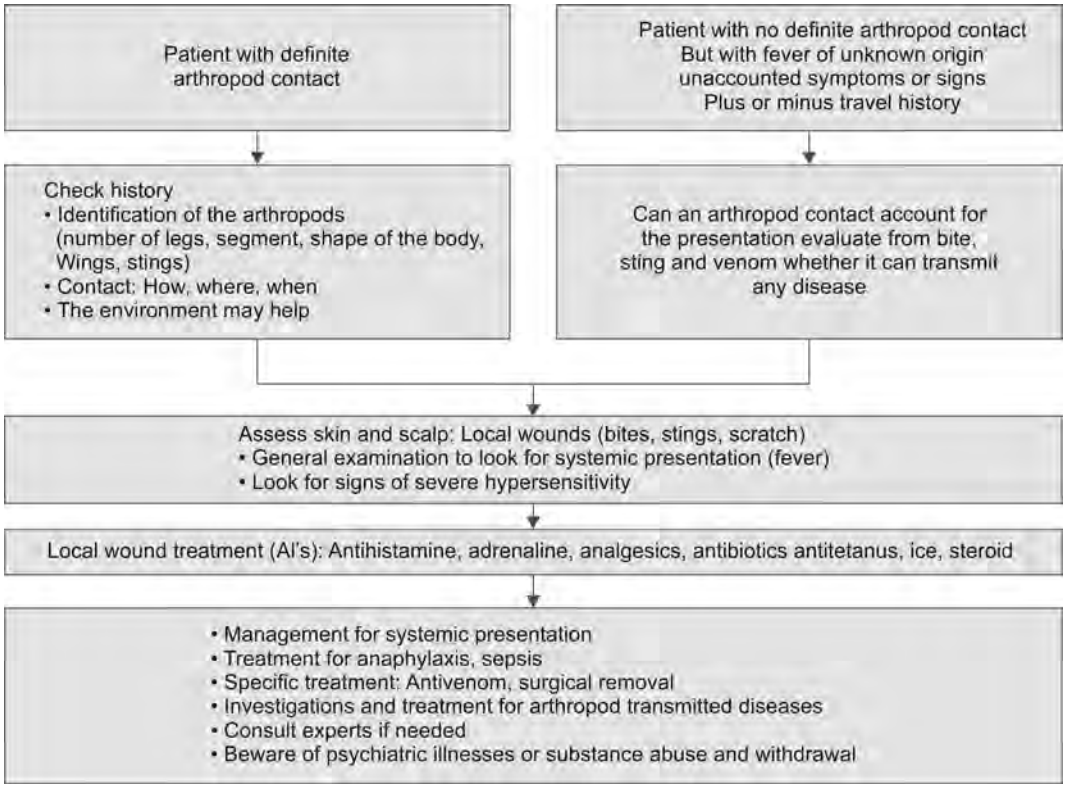
spasm and agitation, Tachyarrhythmias and hypertension to be treated with beta-blockers labetalol and esmolol. Prazosin has found to be effective in hypertensive therapy in children. Advance life support, critical care setting may be required for severe scorpion sting. It is recommended victims with systemic manifestation to be admitted in hospital and those with mild symptoms with localized pain at site of sting can be discharged home with adequate pain medication. Antibiotics to be given if secondary infection. Antivenom to be given if required. Like all animal derived antivenoms immediate and delayed allergic reactions are possible.

SUMMARY

Arthropod contact is common. Contact may cause local wound, systemic presentation, and infection (local and systemic). This chapter is summarized in **Flowchart 1**.

ACKNOWLEDGMENT

Thanks to Dr Quintin Kwok of the Accident and Emergency Department of Queen Elizabeth Hospital, Hong Kong for his comments on the draft of this chapter.



Patient with definite arthropod contact
Patient with no definite arthropod contact But with fever of unknown origin unaccounted symptoms or signs Plus or minus travel history
Check history
• Identification of the arthropods (number of legs, segment, shape of the body, Wings, stings)
• Contact: How, where, when
• The environment may help
Can an arthropod contact account for the presentation evaluate from bite, sting and venom whether it can transmit any disease
Assess skin and scalp: Local wounds (bites, stings, scratch)
• General examination to look for systemic presentation (fever)
• Look for signs of severe hypersensitivity
Local wound treatment (Al's): Antihistamine, adrenaline, analgesics, antibiotics antitetanus, ice, steroid
• Management for systemic presentation
• Treatment for anaphylaxis, sepsis
• Specific treatment: Antivenom, surgical removal
• Investigations and treatment for arthropod transmitted diseases
• Consult experts if needed
• Beware of psychiatric illnesses or substance abuse and withdrawal

FLOWCHART 1: Summary evaluation and management of insect bite.

247
CHAPTER

Marine Envenomation

Deepak Singhal, Devendra Richhariya

INTRODUCTION

Aquatic animals may be venomous and may be dangerous to life of the swimmers, surfers, divers, and fishermen. Most of the victims may not seek medical care because most marine exposures are mild, e.g., mild stings, bites, abrasions, and lacerations. Aquatic animals who produce envenomation through dermal contact are summarized in **Table 1**. Marine envenomation through puncture and laceration is summarized in **Table 2**. Severe and life-threatening envenomation occurs due to box jellyfish, Irukandji jellyfish, cone snails, blue-ringed octopus, stonefish, or sea snakes. In these cases, immediate and effective treatment is given to patient to improve the symptoms (decrease pain, stabilize systemic symptoms, and treat anaphylaxis) and early treatment reduces the secondary complications (local allergic response, infection, and wound complications). Tetanus immunization prophylactic or therapeutic antibiotics are the key for the treatment of all marine envenomation.

SPONGES

Sponges attach to the ocean floor and are acellular creatures. They have spicules of silicon dioxide or calcium carbonate. Sponges such as fire sponge (*Tedania ignis*), poison bun sponge (*Fibularia nolitangere*), and red moss sponge

TABLE 1: Marine envenomation through dermal contact their presentation and treatment.

Marine species	*Clinical presentation*	*Treatment*
Portuguese man-of-war; blue bottle	Local pain, skin blisters, nausea, vomiting, abdominal pain, muscle cramps, and dyspnea	Remove tentacles hot water (upper limit 45°C) immersion
Box jellyfish	Excruciating pain, hypotension, paralysis, respiratory failure, cardiac arrest, skin blisters, and necrosis	Apply acetic acid 5% then remove tentacles, support airway and breathing antivenom if severe symptoms, avoid hot water immersion or pressure immobilization
Irukandji jellyfish	Catecholamine release, muscle pain, abdominal pain, hypertension, troponin leak, heart failure, and pulmonary edema	Remove tentacles, apply acetic acid 5%, cardiac monitoring, blood pressure control (avoid b-adrenergic blockers), respiratory support
Jellyfish	Mild pain, irritant dermatitis	Remove tentacles, apply acetic acid 5%, lidocaine containing product, or hot water (upper limit 45°C) immersion
Sea bather's eruption	Pruritic papules resembling insect bites in distribution of swim suit	Treat skin with acetic acid 5%, or lidocaine-containing first aid remedy, wash swim suit with hot water and detergent, then machine or sun dry
Sea anemone	Erythema and pruritus petechiae, blisters, and ulceration	Acetic acid 5%, may require prolonged wound care
Feather hydroid; fire coral	Stinging pain, urticaria, petechiae, ulceration, and residual hyperpigmentation	Acetic acid 5%, may require prolonged wound care
Sponge	Pruritic irritant dermatitis, blisters, and delayed desquamation	Remove spicules with tape, rubber cement, or facial peel acetic acid 5%
Bristle worm	Painful urticarial rash	Remove bristles with tape, rubber cement, or facial peel, acetic acid 5%

TABLE 2: Marine envenomation through puncture and laceration their presentation and treatment.

Marine species	*Clinical presentation*	*Treatment*
Crown-of-thorns starfish	Dusky puncture wound, pain, bleeding, edema, multiple punctures cause nausea, vomiting, paresthesia	Hot water to tolerance (maximum 45°C) for 30–90 min local anesthetic, locate retained spines, surgical removal if spines near nerve, tendon, or joint
Sea urchin	Red, purple, or black puncture wounds; local muscle aching; edema, multiple punctures cause nausea, vomiting, and paresthesia	Hot water to tolerance (maximum 45°C) for 30–90 min local anesthetic, locate retained spines, surgical removal if spines near nerve, tendon, or joint
Cone snail	Puncture wound resembling bee sting, local cyanosis, limb paresthesia, paralysis, respiratory failure, cerebral edema, coma	Pressure immobilization, support breathing, consider edrophonium, 10 mg IV, for paralysis, consider naloxone, 2–4 mg, for severe hypotension, hot water to tolerance (maximum 45°C) for 30–90 min, local anesthetic, remove retained radula
Blue-ringed octopus	Painless small puncture wounds, facial numbness, paralysis, and respiratory failure	Support breathing, supportive care
Lionfish and scorpionfish	Painful puncture wound, blistering, nausea, and vomiting	Hot water to tolerance (maximum 45°C) for 30–90 min, local anesthetic or nerve block, locate retained spines, surgical removal if spines near nerve, tendon, or joint
Stonefish	Severely painful cyanotic puncture wound, necrotic ulceration, altered mentation, fever, nausea, vomiting, seizures, paralysis, heart block, heart failure, and pulmonary edema	Antivenom for severe envenomation, hot water to tolerance (maximum 45°C) for 30–90 min, local anesthetic or nerve block, locate retained spines, surgical removal if spines near nerve, tendon, or joint, debride necrotic tissue
Stingray	Dusky painful laceration, local hemorrhage and necrosis, barb lodged in victim, large envenomation: nausea, vomiting, muscle cramps, syncope, and arrhythmias	Hot water to tolerance (maximum 45°C) for 30–90 min, local anesthetic or nerve block, locate retained barb, surgical removal of barb, treat retained barb as stab wound if barb in thorax, abdomen, groin, or neck, serial debridement of necrotic tissue
Sea snake	Painless pinhead-sized fang marks, muscle pain and stiffness, nausea, vomiting, ascending paralysis, respiratory failure, muscle necrosis, and renal failure	Pressure immobilization, maintain airway and breathing, antivenom if any symptom, monitor electrolytes and urine output, alkalinize urine if myoglobinuria, dialysis as needed for renal failure and hyperkalemia

(*Mammillaria prolifera*) produce dermal irritants known as crinotoxins. Skin edema, vesiculation, joint swelling, and stiffness are the manifestation of the crinotoxins. Clinical manifestation if mild in nature, reactions subside within 7 days while extensive exposure may induce fever, chills, malaise, dizziness, nausea, muscle cramps, and formication. If spicules remain in the skin, these can result in persistent bullae that take months to heal. Erythema multiforme or dyshidrotic eczema may develop as a delayed systemic complication. In severe cases, surface desquamation may follow. Treatment consists of removal of spicules using adhesive tape, a thin layer of rubber cement, or facial peel. Apply 5% acetic acid (vinegar) soaks. For symptomatic relief steroid cream or an oral antihistamine may be used. For severe allergy, erythema multiforme or dyshidrotic eczema, considers systemic corticosteroids. Antibiotic therapy is considered for wound infections.

HYDROIDS AND FIRE CORAL

Hydrozoans are plumelike species, multiorganism colonies of diverse configurations. Feather hydroids found in tropical waters. Fire coral is identical to hard coral. An example is *Millepora*, distributed in shallow tropical waters and dangling tiny nematocyst-bearing tentacles. The stinging tentacle-bearing Portuguese man-of-war (Physalia physalis) and blue bottle (Physalia utriculus) are widely distributed. Feather hydroids and fire coral clinical manifest as immediate pain and urticaria, progressing to hemorrhagic or ulcerating lesions. Pain usually resolves within 1–2 hours and inflammation resolves by 6–7 days, with occasional residual hyperpigmentation. Pain may persist for hours, and local symptoms resolve within 72 hours. Patient may experience severe systemic symptoms such as nausea, vomiting, muscle cramps, dyspnea, anxiety, abdominal pain, and headache. Treatment for feather hydroid and fire coral envenomation, apply acetic acid 5% (vinegar) to the skin. For symptomatic relief, consider steroid cream or an oral antihistamine; administer systemic corticosteroids, if the reaction is eczematous or indolent. A lidocaine-containing product may be equally effective. Systemic corticosteroid can be used for severe reactions.

JELLYFISH

Scyphozoans are single-organism jellyfish that range in size from 2 cm to 2 m across the bell and have different forms, including free-floating larva, sessile polyp, and large swimming

medusa mauve stingers. Multiple species of stinging larval forms are found in warm waters; the thimble jellyfish larvae are of pinhead-sized. Stinging pain and localized erythema occur when skin comes in contact with tentacles, symptoms resolve in hours to days. Sea bather's eruption occurs when a person comes in contact with the larval forms; pruritic papules occur in a bathing suit distribution (within which larvae are trapped) itching remains for 2–14 days. Fever, headache, chills, malaise, vomiting, conjunctivitis, and urethritis are the other symptoms.

Management includes topical acetic acid 5%, hot water immersion, and corticosteroid or antihistamine cream, and systemic corticosteroid in severe cases. A lidocaine-containing product may be effective as a topical decontaminant. To minimize or prevent sea bather's eruption, change swimwear on leaving the water. Before reuse of swimwear, wash them with detergent and hot water detergent and full drying.

SEA ANEMONES

Sea anemones and soft corals consist of tentacles and have stinging cnidocytes and which secrete mucus that may contain cytolytic and hemolytic toxins, neurotoxins, cardiotoxins, and proteinase inhibitors.

Sea anemones and soft corals envenomation present as painful skin lesions with central pallor and a halo of erythema and petechial hemorrhage, sometimes progressing to vesiculation and necrosis. Fever, chills, malaise, weakness, nausea, vomiting, muscle spasm, and syncope are rare. Mild envenomation resolves within 48 hours. Severe reactions may become indolent, leading to hyperpigmentation, hypopigmentation, or keloid formation. Severe dermatitis may require prolonged wound care with debridement and antibiotics for secondary infection.

BOX-SHAPED JELLYFISH

Some box-shaped jellyfish found in tropical waters are highly venomous, e.g., Hawaiian box jellyfish, Japanese box jellyfish, and Australian box jellyfish, each delivers potentially deadly venom. Irukandji jellyfish are 1–2.5 cm box jellyfish. The "Irukandji syndrome" is local vasoconstriction and high blood pressure attributed to sympathetic nervous system stimulation. Box jellyfish stings cause excruciating with rapid blistering, muscle spasm, hypotension, and sometimes paralysis. Victims may have respiratory failure and cardiac arrest within 1–2 minutes. Most deaths occur 5–20 minutes after the sting. Skin necrosis is common. Symptoms begin in 20–30 minutes poststing with muscle pain, abdominal and chest pain, nausea, vomiting, and respiratory failure in Irukandji envenomation. Massive catecholamine release precipitates severe hypertension and tachycardia, leading to cardiomyopathy, pulmonary edema, cerebral edema, troponin leak, and hypokinetic heart failure.

If box jellyfish sting is suspected, airway support should be provided with artificial ventilation. Sting sites should be poured with 5% acetic acid (vinegar) immediately for at least 30 seconds before removing adherent tentacles. Administer specific antivenom one vial intravenous (IV) or three vials intramuscular (IM) at three different sites. Repeat as needed every 10 minutes up to three times immediately and then once or twice every 2–4 hours until there is no further progression of systemic symptoms. Antivenom use is under scrutiny because of poor efficacy noted during in vitro studies. However, until further notice, it remains recommended. For Irukandji envenomation, treatment measures are supportive therapy, serum troponin, and cardiac monitoring should be done.

ANNELID WORMS

Bristle worms that easily penetrate skin and are covered with chitinous bristles. When they come in human contact cause bristles to break off into the skin, causing pricking sensation and urticarial rash with rare necrosis. Pain subsides in a few hours, but urticaria may persist for 2–3 days and skin discoloration for up to 10 days. Secondary infection and cellulitis may occur. Bristles should be removed with the help of tape, facial peel, or a thin layer of rubber cement. Next, apply acetic acid 5% soaks. Consider an oral antihistamine or corticosteroid for severe inflammatory reaction.

STARFISH AND SEA URCHINS

Starfish and sea urchins are included in the phylum Echinodermata. The crown-of-thorns starfish produces a toxic slime which is poisonous and that coats the spines. Toxic slime causes are hemolysis, myonecrosis, hepatotoxicity, and anticoagulation. Sea urchins have venom-bearing globular bodies covered by calcified spines have rounded at the tip or hollow. Venom of sea urchins contains steroid glycosides, hemolysins, proteases, serotonin, and cholinergic substances.

Crown-of-thorns starfish causes puncture wounds with immediate pain, bleeding, and edema on the skin. Wounds become dusky and tenosynovitis may develop. Multiple punctures can cause systemic reactions with paresthesia, nausea, vomiting, lymphadenopathy, and paralysis. Pain persists for 30 minutes to 3 hours. Retained spines can cause granulomas. Painful puncture wounds with severe local muscle aching lasting up to 24 hours are the hallmark of sea urchins' venom. Frequently, spines break off within the skin and can cause synovitis. Systemic symptoms include nausea, vomiting, paresthesia, and infections are common.

Treatment includes immersion of puncture wounds in hot water to tolerance (upper limit 45C) for 30–90 minutes or until there is significant pain relief. Nerve block or local anesthetic infiltration may be required for pain control. Wounds should be irrigated and explored for spines and should be removed as soon as possible. Surgeon should be consulted if spines have entered a joint or in close to neurovascular structures. For spine localization and removal, radiography, ultrasound, computed tomography, or magnetic resonance imaging (MRI) may be helpful. Reactive neuropathy may respond to a systemic corticosteroid. Secondary infections are common. Retained spine fragments causes granulomas and should be removed by excision or ablation, and retained spines may also cause arthritis which requires synovectomy.

MOLLUSKS

Cone snails are shelled mollusks. Venom-containing radular tooth stabs the victim and causes envenomation. Conotoxins target receptors and channels that mediate neuromuscular blockade. Blue-ringed octopuses are characterized by

presence of iridescent blue rings, are found in shallow waters of Indo-Pacific oceans. Venom is injected through parrot-like beak that causes paralysis. Bee sting–like puncture wound with local cyanosis occurs due to cone snails. Local paresthesia may be extended as paralysis that can lead to respiratory failure within 1 hour. Nausea, blurred vision, malaise, and weakness for a few hours occur in mild stings. Severe envenomation-induced paralysis lasts for 12–36 hours and takes weeks for symptom resolution. Blue-ringed octopus bites create one or two small puncture wounds that often go unnoticed. Within 15 minutes, oral and facial numbness begin that may rapidly progress to paralysis and respiratory failure. Cardiac arrest may follow. Other symptoms include numbness and discomfort of the affected limb, nausea, vomiting, and chest tightness. Cardiovascular and respiratory support takes priority in the management of cone snail envenomation. Pressure immobilization is recommended during transport. Edrophonium (10 mg IV adult dose) can be given for paralysis. Adverse reactions to edrophonium are treated with atropine, 0.6 mg IV. If hypotension use of naloxone, 2–4 mg, has been suggested. The wound should be irrigated with hot water to tolerance (upper limit 45°C) for 30–90 minutes and foreign bodies (radula) should be removed. Consider local anesthetic injection. Treatment of blue-ringed octopus bite centers on cardiovascular and respiratory support. Provide artificial ventilation if paralysis occur. Paralysis lasts after 4–10 hours, paralysis recovers, and hypoxia improves rapidly with complete recovery in 2–4 days.

SCORPIONFISH

Scorpionfish comes under family Scorpaenidae, these species have spines and venom glands covered by integumentary sheaths. With increasing order in toxicity lionfish are the least toxic, followed by scorpionfish with moderate toxicity, and stonefish with potent toxicity. Lionfish is very attractive, with long slender spines. Venom may induce local paresthesia and paralysis. Scorpionfish are camouflaged against their surroundings (ocean bottom and rocks) and have medium-length spines. Scorpionfish venom highly toxic to connective tissue, causes hypotension and pulmonary edema, and can cause paralysis. Stonefish remain motionless, hide, and possess short stout spines. Pain is main presenting features, starts immediately, and peaks at 60–90 minutes. With serious envenomation, pain may cause delirium and persist for hours (scorpionfish) or days (stonefish). The puncture wound is initially ischemic and cyanotic with progressive vesiculation, tissue sloughing, cellulitis, and necrotic ulceration. Systemic manifestations include anxiety, headache, skin rash, fever, nausea and vomiting, diarrhea, abdominal pain, seizures, paralysis, pericarditis, atrioventricular block, congestive heart failure, and pulmonary edema. Death from a stonefish sting can occur within the first 6–8 hours. Wounds healing occur in 4–8 weeks.

The wound should be immersed in hot water to tolerance (upper limit 45°C) for at least 30–90 minutes. Consider local anesthetic infiltration or regional nerve block. The wound should be thoroughly cleansed. If the spine has penetrated deeply into the sole of the foot or hand, surgical exploration should be performed. In a case of severe systemic reaction, stonefish antivenom may be administered IV or IM. As a rough estimate, one vial of antivenom should neutralize one or two significant punctures, with additional vials administered for recurrent severe pain or systemic manifestations.

STINGRAYS

Stingrays are flat cartilaginous fish with caudal appendages with bilateral retro serrate barbs and associated venom glands. Venom contains serotonin, 5'-nucleotidase, and phosphodiesterase. Toxin may induce peripheral vasoconstriction, bradycardia, tachycardia, atrioventricular block, and seizure activity.

Stingray envenomation can cause large lacerations, most often on lower extremities. There is intense pain, edema, and bleeding peaking at 30–60 minutes and lasting up to 48 hours. The wound starts with dusky coloration and may progress to hemorrhagic necrosis. Systemic manifestations include weakness, nausea, vomiting, diarrhea, diaphoresis, muscle cramps, headache, syncope, seizures, and arrhythmias. Treatment mainly consists of measures of pain relief, soak in hot water to tolerance (upper limit 45°C) for 30–90 minutes. Narcotics, local anesthetic infiltration, or a nerve block may be needed. The wound should be irrigated and debrided, and imaging should be obtained to rule out a retained spine. If a spine is lodged in the chest, abdomen, or other vital structure, it should remove surgically in the operating room. Wounds are preferably treated with delayed primary closure and should be observed closely because ulceration, necrosis, and secondary infection are common.

SEA SNAKES

Sea snakes are found mostly in tropical Pacific and Indian oceans. Sea snake venom contains hemolytic and myotoxic compounds (peripheral neurotoxins acting at the acetylcholine receptor), and causes muscle necrosis, hemolysis, and renal tubular damage. Sea snake species, which cause serious envenomation, are *Astrotia stokesii*, *Enhydrina schistosa*, *Hydrophis ornatus*, *Hydrophis cyanocinctus*, *Lapemis hardwickii*, *Thalassophina viperina*, and *Pelamis platurus*. Because fangs are short and easily dislodged, approximately 80% of bites do not result in envenomation. Presentation sea snake bites cause minimal pain and may resemble mere pinpricks. Nausea, muscle stiffness, swallowing dysfunction, blurry vision, and paralysis occur within 30–60 minutes. There has rarely been envenomation, if symptoms do not develop within 6–8 hours. Life-threatening complications include respiratory distress, paralysis, electrolyte disturbances, and myoglobinuria with acute renal failure leading to death. Treatment includes pressure immobilization during transport. Administer sea snake antivenom IV as soon as possible. Anticipate respiratory failure and provide mechanical ventilation. Hyperkalemia, rhabdomyolysis, and renal dysfunction are common so monitoring of serum electrolytes and renal function is important. If myoglobinuria is detected, alkalinize urine with sodium bicarbonate and administer diuretics. Acute renal failure may require dialysis.

TREATMENT AND COMPLICATIONS

Antivenom and Anaphylaxis

An envenomation or antivenom administration can cause anaphylaxis and presents as hypotension, bronchospasm, facial and airway swelling, pruritus, urticaria, nausea, vomiting, and diarrhea. Most reactions occur within 15–30 minutes and nearly all occur within 6 hours. A recipient of antivenom should be pretreated with 50–100 mg of IV diphenhydramine (1 mg/kg in children). Antivenom should be administered one vial over 5 minutes. If anaphylaxis develops, after antivenom injection, 0.1- to 0.2-mL aliquots of antivenom should be alternated with 0.03- to 0.1-mg IV doses of epinephrine, or an epinephrine drip administered (maintain heart rate <150 beats/min).

Serum Sickness

Serum sickness presents with fever, arthralgias, malaise, urticaria, lymphadenopathy, rashes, peripheral neuritis, and swollen joints. Formation of IgG antibodies in response to antigens in antivenom causes deposition of immune complexes that induce vascular permeability, activate complement, degranulate mast cells, and trigger release of proteolytic enzymes. Serum sickness is managed with systemic corticosteroids until symptoms resolve, followed by a 2-week taper.

SUMMARY

It is important to know the marine creatures in our clinical practice area. Every emergency physician should be able to manage anaphylaxis or acute life-threatening envenomation from box jellyfish, Irukandji jellyfish, stonefish, cone snail, blue-ringed octopus, or sea snake. If marine envenomation is suspected, evaluation is performed as summarized in **Box 1**. Know where to obtain antivenom. Immediate topical decontamination followed by removal of tentacles is helpful. Provide adequate medication for pain control. Early initiation of appropriate antibiotics is helpful in controlling the secondary infection caused by marine bacteria. Various therapeutic options (pharmacologic, nonpharmacologic, and surgical) to manage marine envenomation are summarized in **Table 3**.

BOX 1: Evaluation and management marine envenomation.

Immediate evaluation

- ABCs
- Attempt to identify causative agent
- Consider the geographic location where the injury took place, wheal and flare reactions are nonspecific
- Bug bite–type reaction located in areas of a swimsuit is classic for sea bather's eruption
- A gaping laceration, particularly of the lower extremity, with cyanotic edges suggests a stingray wound
- Multiple punctures in an erratic pattern with or without purple discoloration or retained fragments are typical of a sea urchin sting
- Fang marks with weakness, respiratory paralysis, myalgias, blurred vision, and vomiting indicate a sea snake bite
- An ischemic puncture wound with a red halo and rapid swelling and pain not relieved by hot water immersion suggests scorpionfish envenomation
- Blisters often accompany a lionfish sting. Painless punctures with rapid neuromuscular paralysis suggest a blue-ringed octopus bite The site of a cone snail sting is punctate, painful, and ischemic
- Rapid (within 24 hours) onset of skin necrosis suggests an anemone sting
- "Tentacle prints" with cross-hatching suggest a box-jellyfish envenomation
- Hypertension, muscle aches, and vomiting suggest Irukandji syndrome
- Ocular, intraoral, or genital lesions may come from fragmented hydroids, coelenterate tentacles, or Scyphozoans larvae
- Decontaminate (specific to causative organism)
- Stabilize and treat

Long-term recommendations

- Prevention:
  - Do not touch marine life when snorkelling, diving, or swimming. Avoid touching the bottom or grasping ledges or overhangs
  - Wear protective gear that covers all exposed skin
  - Shuffle feet when walking in shallow sandy areas
  - Do not stand or walk on reefs
  - Life-threatening envenomation benefits from rapid decontamination and cardiopulmonary support, and may benefit from antivenom administration
  - Provide tetanus prophylaxis in all cases and have a low threshold for initiating antibiotics
  - Marine envenomation often heals slowly and poorly, so arrange for follow-up

TABLE 3: Therapeutic options for marine envenomation management.

Nonpharmacological options		
Option	*Indication*	*Use*
Hot water immersion	• Jellyfish • Stingrays • Venomous spined fish	Hot water to tolerance (maximum 45°C); immerse for 30–90 min or until pain relief; check water temperature frequently
Adhesive tape, rubber cement, and facial peel	Sponge bristle worm	Apply gently over wound and peel to remove spicules or bristles
Pressure immobilization	Cone snail sea snake	Wrap an elastic bandage with a wide margin over the envenomation site at venous-lymphatic occlusive pressure; keep the limb immobile
Scrape with razor	Jellyfish, fire coral, hydroid, and anemone	Apply a layer of shaving cream and scrape with a razor to remove nematocysts
Pharmacologic option		
Drugs	*Indications*	*Doses*
Acetic acid 5% (vinegar)	All-purpose skin sting decontaminant	Apply topically
Lidocaine or bupivacaine without epinephrine	Local anesthetic infiltration or nerve block for pain control	Lidocaine, max dose 3 mg/kg bupivacaine, max dose 2.5 mg/kg
Prednisone (or equivalent corticosteroid)	Severe local inflammation or allergic reaction	60–100 mg PO QD adults 2–5 mg/kg (max dose 50 mg) children PO QD tapered over 10–14 day
Hydrocortisone 1% cream	For local inflammation and symptomatic relief	Apply BID
Antibiotics	Prophylaxis for puncture wounds and at first sign of infection Should cover *Staphylococcus*, *Streptococcus*, and microbes of marine origin, such as *Vibrio*	Ciprofloxacin, 500 mg PO BID Trimethoprim/ sulfamethoxazole, 160/800 mg PO BID doxycycline, 100 mg PO BID
Stonefish antivenom	Hyperimmune horse globulin preparation used to neutralize stings of stonefish	*Initial dose*: One vial per two puncture wounds, repeat for recurrent pain
Box jellyfish antivenom	Hyperimmune sheep globulin preparation used to neutralize the stings of *Chironex fleckeri* and *Chiropsalmus*	• *Initial dose*: 1 vial IV or three vials IM • Repeat up to three times every 10 min as needed, and then every 2–4 h until no further worsening
Sea snake antivenom	Hyperimmune horse globulin preparation used to neutralize the bites of most sea snakes	*Initial dose*: 1–3 vials Up to 10 vials may be required
Surgical treatment options		
• Debridement • Spine extraction or laser ablation • Tendon repair, synovectomy, or granuloma removal

248
CHAPTER

Preparation for International Travel

Neeraj Mangla, Sahanya Ramesh Shetty

INTRODUCTION

About 1 billion tourists have travelled across the globe in the initial 9 months of 2016. This data has a 4% spike when compared to 2015. According to the World Travel and Tourism Council, this number is likely to increase to 1.8 billion people travelling internationally in the year 2025. It is estimated that approximately 22–64% of the international travelers will experience ailments such as respiratory tract infection, gastrointestinal diseases, and/or skin infections based on the country or continent they had visited. The extent of the disease cannot be anticipated; however, such situations can be avoided if consulted prior to the date of travel with a healthcare practitioner. An average traveler during a 2-week trip may lose an average of 3 days due to ailments acquired during or post travel. About 20% of them continue to in poor health after their trip and 10% of them require medical help for their condition. However, with the current situation of global pandemic this study cannot be held valid. The near future does not hold valid for the calculations of the past. In every 100,000 international travelers, it is observed that 50,000 people contract an illness during the travel. While 8,000 people need to seek medical attention, of which 5,000 are in need to be confined to rest. About 300 people are hospitalized for medical intervention, 50 travelers require to be evacuated by air transportation, and 1 patient dies.

However, with the current situation of global pandemic of coronavirus disease-2019 (COVID-19) this study cannot be held valid. The near future does not hold valid for the calculations of the past. As per the World Health organization (WHO) statement released on 30th January 2020, the Director-General of the WHO, following the advice of the Emergency Committee convened under the International Health Regulations (2005), declared the current outbreak of COVID-19 a public health emergency of international concern and issued Temporary Recommendations.

CONSIDERATIONS: PRIOR TO TRAVEL

In most of the situations, travelers across the globe underestimate the health and safety risks involved. In very few cases, an international traveler seeks consultation about proper travel counseling prior to the date of departure. People travelling to higher risk countries to meet relatives or family members are more prone to contract gastrointestinal infections along with malaria and dengue fever. They tend to stay for longer periods, eat local food, and do not practice safe hygienic methods as a precaution. They neglect the severity of the contractible disease and pretravel counseling and safety measures. There is link between those avoided pretravel consultation and then contracting diseases like malaria, leading to consequences on health of travelers. Pretravel counseling includes individual approach on risk assessment, immunization schedule reviewed, details of arthropod-related diseases and protective measures, prophylaxis for malaria, traveler's diarrhea along with risk reducing measures, and travel-related education. This serves to be a helpful aid to a person travelling to developing countries, for adventure sports or activities, extended travel plan, travelling with a chronic medical condition or immune-compromised state, and travelling with children or pregnant mothers. It is ideal to undertake a medical consultation at around 6 weeks before the date of departure. This enables adequate time for the effect of immunization and preparation. However, it is obvious that medical attention can be taken at any time of travel during transit or stay or even after returning back to the maiden country.

RISK ASSESSMENT: INDIVIDUAL APPROACH

Factors that must be considered during analysis of individual risk assessment of a traveler:

- Country of destination
- Time of stay
- Season at the time of travel
- *Medical condition of the traveler*: It should include the complete list of medications taken currently, immunization status, any disabilities, previous history of surgeries, allergies history, and pregnancy status or postpartum.
- Any past history of traveler
- *Activities during the period of stay*: Attending mass gatherings, accommodation, and financial aids for medical help.

IMMUNIZATION: PRIOR TO TRAVEL

Pretravel Immunization

Proper screening of all travelling persons should be done at least 6 weeks before the date of departure after a step by step assessment of previous and current immunization. Additional immunization may be required specific to the destination (**Table 1**). All travelers should be screened to determine their need for pretravel immunizations including a review of their current immunization history. In addition to routine or domestic vaccinations, additional destination-specific vaccinations may be required activities and duration of stay. Please note that due to associated risks to health, live vaccines cannot be administered to pregnant mothers and immune compromised patients such as measles, mumps, rubella, oral dose of polio, rotavirus, varicella zoster, influenza, typhoid fever, yellow fever, Bacillus Calmette–Guérin (BCG) [for tuberculosis TB]. Administration of live vaccinations should be either 4 weeks apart or the same day, to prevent chances of failure.

Routine Vaccination

International travelers are more prone to contract vaccine preventable diseases such as influenza and hepatitis A, when compare to more country-specific vaccine preventable diseases like typhoid or Japanese encephalitis. As a result, it is more beneficial for a person travelling internationally to review with their current immunization status and ensure adequate booster dose, if required before travelling to other countries.

ARTHROPOD-SPECIFIC PROTECTION GUIDELINES

Arthropods such as mosquitoes, ticks, flies, and chiggers aid to the transmission of infections such as malaria, dengue fever, and rickettsia diseases. These diseases are primarily prevented by protective measures and maintaining adequate sanitary conditions around them. These types of infection are the most common cause of systemic febrile illness presented by patients after they return back home. A large number of risk factors include the destination of travel (urban or rural, developing countries), duration of stay, season (rainy and monsoon), and type of accommodation (overcrowded spaces and endemic areas). The female anopheles mosquito tends to bite between dusk and dawn. However, other vectors such as mites and ticks bite all day and night. Preventive and protective methods must be practiced in order to reduce the possible chances of acquiring arthropod-specific infection during the course of travel (**Table 2**).

TABLE 1: Routine vaccinations for travelers.

Standard vaccination	*Indication*	*Route*	*Scheduled dose*	*Accelerated dose*	*Estimated time of protection*
Haemophilus influenzae type b	• Infants/adults asplenia • Sickle cell disease leukemia—after chemotherapy or bone marrow transplant • 5–18 year: HIV patient	IM	• Three to four doses: At 2nd, 3rd, and 6th months and between 12th and 15th month • Three to four doses: 2, 4, 6, and 12–15 months		
Hepatitis A (inactivated virus)	Age >1 year	1 mL, IM	• First dose: Day 0 • Second dose: 6–12 months	• Combined dose • Hepatitis A and hepatitis B	• More than 20 years (seropositivity) • More than 40 years (antibody modeling)
Hepatitis B (recombinant hepatitis B surface antigen)	All international travelers	IM	• First dose: Day 0 • Second dose:1 month • Third dose: 6 months	• Combined dose • Hepatitis A and hepatitis b	30 years
Combined hepatitis A and B: Inactivated virus and recombinant hepatitis B antigen	Age >1 year	1 mL, IM	• First dose: Day 0 • Second dose: First month • Third dose: 6 months	• First dose: Day 0 • Second dose: 7th day • Third dose: 21st day • Fourth dose: 12 months	More than 15 years
Herpes zoster (shingles)	Geriatric (older than 60 years)	SC	Single dose		
Human papilloma virus (HPV)	Children and young adults	IM	• First dose: Day 0 • Second dose: 1–2 months • Third dose: 6 months		

Continued

Continued

Standard vaccination	Indication	Route	Scheduled dose	Accelerated dose	Estimated time of protection
Influenza (inactivated virus or recombinant, trivalent or quadrivalent)	Age >6 months	0.5 mL, IM 0.1 mL, ID	Single dose	NA	1 year
Influenza (live-attenuated virus and quadrivalent)	Age >6 months	0.1 mL in each nostril	Single dose	NA	1 year
Measles, mumps, and rubella (MMR) (live-attenuated virus)	All international travelers	0.5 mL, SC	• First dose: Day 0 • Second dose: Fourth week		Lifetime, if two doses are administered at any time in life
Meningococcal disease (quadrivalent ACYW-135, bacterial polysaccharide, conjugated DNA)	• As a routine at 11 and 12 years • Booster at 16 years • Travel to belt of meningitis: Africa or Saudi Arabia (for pilgrimage)	0.5 mL, IM	Single dose	NA	3–5 years
Pneumococcal disease	• Infants • Adults: More than 60 years	IM/SC	• Infant: • First dose: 2nd month • Second dose: 4th month • Third dose: 6th month • Fourth dose: Between 12th and 15th month		
Poliomyelitis (inactivated virus)	• Travelers to countries with ongoing transmission • More than 4-week travel to Afghanistan or Pakistan	0.5 mL, SC	If previously immunized: Single dose	NA	Lifelong, if primary dose + booster at 18 years or more
Rotavirus	Infants	Oral	• First dose: 2nd month • Second dose: 4th month • Third dose: 6th month		
• Tetanus, diphtheria, and pertussis • Acellular pertussis (Tdap) or tetanus-diphtheria (Td): Toxoid and protein antigen	All international travelers	0.5 mL, IM	If previously immunized: Single dose	NA	• 10 years • 5 years for traveler—adventurous activities, injuries, in places with substandard medical care
Varicella (chicken pox)	All international travelers	SC	• Below 13 years • First dose: 12th–15th month • Second dose: 4–6 years • Above 13 years: Two doses at 28 days apart		
Typhoid (bacterial cell wall polysaccharide)	Travel to low income nation	0.5 mL, IM	Single dose	NA	2–3 years

Continued

Continued

Yellow fever (live-attenuated virus)	• Travel to endemic area (tropical countries: South America and Africa) • Avoid in children <9-month-old	0.5 mL, SC	Single dose	NA	10 years
Cholera (Live attenuated bacteria)	Adults 18–60 years High risk	1 sachet, oral	Single dose	NA	3–6 months
Japanese encephalitis inactivated virus, from cell culture	Travel to endemic areas	0.5 mL, IM	• First dose: Day 0 • Second dose: Day 28	• First dose: Day 0 • Second dose: Day 7	• 1–2 years after initial dosage • More than 6 years if boosted at 1–2 years
Rabies	Travel to rabies infested zoo, extended stay	IM	3 doses before exposure: 0, 7, and 21–28 d	Two additional doses (days 0 and 3) after exposure	Rabies travelers to rabies enzootic areas (especially remote, rural, or extended stay)
Tick borne encephalitis	Travelers to Europe, Soviet Union, and Asia	IM	Three doses: Day 0, 1–3 months, and 5–12 months	3 years	
Tuberculosis (BCG)	To be considered in healthcare workers travelling to high risk areas, with isoniazid and rifampicin	ID	Single dose	10–15 years	

Note: Meningococcal and poliomyelitis are childhood vaccines that may require boosters in adult travelers with specific itineraries.

(BCG: Bacillus Calmette–Guérin; DNA: deoxyribonucleic acid; HIV: human immunodeficiency virus; ID: intradermal; IM: intramuscular; SC: subcutaneous)

TABLE 2: Preventive and protective methods for arthropod infections.

Practice precluding	• Avert from regions endemic to malaria or outbreaks • Avert areas with water pooling or stagnant water bodies collecting and vegetations around the place of accommodation (chiggers/ticks) • Try to avoid travelling outside during dusk and dawn
Background check	• Prior check of type of accommodation and surrounding area • Check for rooms with adequate ventilation and air conditioning • Close the windows at the time of sunset
Garment check	• Avoid exposing areas of skin: Wear long sleeved shirts, jackets, or coats • Clothes of lighter shades and heavy weighted to prevent mosquito bites, sand flies, or tsetse flies
Additional insecticide application	• Application of permethrin on garments (shirts, t-shirts, and jackets), shoes, and camping gear • Carry insecticide impregnated clothing • Reapply insecticide after 5 washes
Application of repellent	• Repellent-containing diethyltoluamide (DEET) (20–50%) or picaridin (20%) can be applied over hands, palms, face, forearms, and legs and feet • Reapply after 6–8 h of DEET and every 4 h for picaridin • Day time application for *Aedes* mosquitoes and night time for *Culex* and *Anopheles* mosquito • Safe in pregnancy and infants above 2 months of age
Bed nets with insecticide impregnated	• Practice sleeping under bed nets impregnated with pyrethroid in countries endemic for malaria • Retreatment of nets for effectiveness • Can be used for months
Insect repellents	Use repellents such as mosquito coils, candles, plastic strips, heat generating equipment, and insecticide spray at the time of dusk
Tick check	Full-body and clothing check after activity and at the end of the day, using a mirror or companion

MALARIA—CHEMOPROPHYLAXIS

Chemoprophylaxis is highly recommended to travelers to endemic regions in order to prevent malaria since there is no definitive vaccine for malaria (**Table 3**). Immunocompromised patients, asplenic or human immunodeficiency virus (HIV), are under higher risks of being infected with malaria. They would have more serious consequences compared to the general population. The course of treatment is started few weeks before travel and continued after return depending upon the efficacy of the drug. Avoiding taking proper doses of prophylaxis can pose as one of the many causes of being infected by malaria.

TRAVELER'S DIARRHEA

Traveler's diarrhea affects about 10–20% of international travelers during the first 2 weeks with presenting symptoms lasting for an average of 3 days. Route of transmission if fecal-oral, with bacterial case accounting for 80–90% cases. Use of antacids and proton pump inhibitors (PPIs) causes

TABLE 3: Chemoprophylaxis for malaria.

Drug	*Typical adult dosing*	*Typical pediatric dosing*	*Start (preexposure)*	*Continue (postexposure)*	*Advantages*	*Disadvantages*
Chloroquine	500 mg salt (300 mg base) oral once a week	8.3 mg salt (5 mg base)/kg/week up to the adult dosage	2 weeks	4 weeks	• Safe and well tolerated • Can be used during pregnancy • Can be used in children (all ages)	• Global resistance outside of the Caribbean and Central America • May exacerbate psoriasis
Doxycycline	100 mg oral once a day	2 mg/kg/day up to adult dosage (for children ≥8 years) up to the adult dosage	2 days	4 weeks	• Least expensive • Can prevent leptospirosis and rickettsia • Good last-minute choice • Widely available globally	• Esophageal irritation/ulceration • Skin photosensitivity • Vaginal yeast infections • Not for use in pregnancy and children <8 years old
Mefloquine	250 mg salt (228 mg base) oral once a week	• ≤9 kg: 5 mg/kg (4.6 mg/kg base) once per week • >9–19 kg: One-fourth of 250-mg tablet weekly • 20–30 kg: One-half of 250-mg tablet weekly • 31–45 kg: Three-fourths of 250-mg tablet weekly • >45 kg: 250 mg once per week	2–3 weeks	4 weeks	• Weekly dosing • Good long-term regimen • Can be used during pregnancy • Can be used in children (all ages)	• Some areas of mefloquine resistance (Southeast Asia) • Neuropsychiatric side effects • Avoid in patients with depression, psychosis, seizures, and atrioventricular conduction abnormalities
Atovaquone/Proguanil	250 mg atovaquone/100 mg proguanil oral once a day	• 5–8 kg: One-half of a children's tablet (62.5 mg atovaquone/25 mg proguanil) daily • 9–10 kg: Three-fourths of a children's tablet daily • 11–20 kg: 1 child's tablet daily • 21–30 kg: 2 children's tablets daily • 31–40 kg: 3 children's tablets daily • >40 kg: 1 adult tablet daily	2 days	1 weeks	• Well tolerated • Good for short trips • Good last-minute choice • Can be used in children (≥11 kg) and off-label in children (≥5 kg)	• Expensive • Avoid with renal impairment • Not recommended for pregnant women, breastfeeding mothers, and children <5 kg

reduced gastric acidity making the travelers more prone to gastrointestinal infections. Immunocompromised patients, pregnant mothers, and young children are at a higher risk of contracting the disease.

Recommendations for Safe Travel

- Avoid eating at restaurants with poor sanitation and unhygienic conditions.
- Avoid raw food, uncooked fish or meat, eggs shellfish, or mayonnaise.
- Always consume bottled or packaged water. Ensure the source of water is disinfected and water is filtered and treated well.
- Consume well-cooked meals.
- Avoid eating from street vendors or locally from market stalls. Avoid eating cut fruits, salads, and cold sauces.
- Consume dairy products that are pasteurized.
- Avoid consuming unrefrigerated or nonpackaged food.
- *Proper hand hygiene*: Washing hands with soap and water can reduce the risk of travelers' disease by 30%. If not available, 60% alcohol-based sanitizer can be used.
- Prophylaxis is not routinely recommended.

Self-treatment

- *Mild dehydration*: Encourage oral fluids like water or unsweetened juices to replenish the loss of water due to dehydration. Avoid Gatorade or soft drink due to their high sugar content and low salt content.
- *Moderate-to-severe dehydration*: Oral rehydration salts (ORS) are ideal for adequate rehydration, which is available in markets or can be made at home too. ORS is prepared by mixing half a teaspoon of salt and six level teaspoons of sugar to 1 L of bottled water. Early treatment of diarrhea with antibiotics and adequate hydration is effective in reducing the prolongation of duration of symptoms.
- *Severe diarrhea*: Consider single dose of quinolone (tablet ciprofloxacin 500 mg or levofloxacin) or tablet azithromycin 1 g for rapid cessation. In Southeast Asian countries, azithromycin is preferred due to fluroquinolone-resistant enteropathogens.

PREVENTION OF INJURY

Injuries are preventable to a certain extent; however, recent studies show that international or domestic travelers are more prone to injuries than acquiring an infection. Among the most common deaths, road traffic accidents account for 56% and drowning about 25%. One is three times more prone to drown in an overseas country than at home. Travelers are around new surroundings and situations in a foreign land. Hence, it is more likely that they are injured in road traffic accidents, especially during monsoon (heavy rainfall), at night, or during national and public holidays.

Precautionary Measures

- Restrict travel time during the night time to unknown locations, especially without the presence of local travel guide. Look out for excessive fog, rain, and snow at the destination or during travel.
- If you have an infant/children travelling, carry child safety seats (in most of the countries it is not mandatory to have car seats for infants and toddlers).
- Collect basic information about the transport vehicle and ensure airbag safety and functional seatbelts. Wear seatbelt at all times during the journey and give preference to sit at the backseat.
- Restrict using two wheelers for transportation. If so, ensure you wear properly fitting helmet and safety gears.
- As legally mandated, avoid driving under the influence of alcohol and/or with someone who has consumed alcohol or other recreational drugs.
- Pedestrians often do not follow precautions while crossing the road or walking on the causeway. In addition, avoid using roads with limited visibility for commuting.
- Avoid travelling in cars, minivans, buses, or two wheelers overcrowded with passengers.
- For water sport activities, ensure floating devices are available at the location or carry them beforehand, if possible. Constant look out for children around water bodies such as lakes, ponds, river streams, or at the beach. Supervision should be by an adult not under the influence of alcohol. Do not participate in water sport activities after consumption of alcohol. Prior homework about the location, safety guidelines of water sports, and weather conditions should be done.

TRAVEL WITH CHILDREN/INFANT

In children, acute diarrheal diseases lasting up to 2 weeks are the most common cause of gastrointestinal infections, especially bacterial (one-third of all cases).

Precaution Prior to Travel

- Adopt the principle of cleaning, boiling, and cooking before consuming any food products in a foreign land.
- Adopt the practice of hand sanitization and hygiene at regular intervals.
- Most cases of moderate dehydration associated with gastroenteritis can be treated with adequate rehydration. ORS is adequate and ideal for most conditions.
- Antiemetics should be prescribed for children with symptoms of nausea or vomiting.
- Due to its lower resistance rates, azithromycin is more preferred in comparison to fluoroquinolones (same as in adults).
- *Malaria in endemic areas*: Follow malaria and arthropod specific guidelines as discussed earlier in this chapter. Bed should be covered with adequate nets; permethrin-treated clothing should be worn at most of the times during dusk, dawn, or daytime. Wear long-sleeved shirts or T-shirts, cover most parts of body with either socks for the feet or scarf around the neck. Local application of diethyltoluamide (DEET) (25–50%) and picaridin (KBR3023) (20%) over the exposed areas of skin is carried out as a preventive measure for children. Pay attention to areas around mucous membranes and hand in children. A combination of permethrin and insect repellent coils or devices can be very helpful in prevention of breeding of mosquitoes in the surrounding.

- Administration of medicines are challenging in younger patients. As a result, crushing medicines and mixing with juices, peanut butter, yogurt, or other thicker, sweet foods, or water can be effective in removal of the bitter taste.
- Prior check with the airlines for restraint seats availability for children/infants/toddlers.
- Children and infants are more prone to motion sickness in longer durations of travel. Symptoms such as ataxia are predominant in children <5 years, whereas, older children have classical complains of headache, vomiting, nausea, pallor, and dizziness with sweating.
- Make sure the child is fed at least 3 hours prior to the start of travel and maintain a stable head and body posture to decrease the effects of sickness during travel.

JET LAG

The phenomena of jet lag are based on rapid difference in time zone while traversing different countries which gets affected. The internal clock—circadian rhythm versus the day night cycle in external environment is altered to an extent that the body is unable to cope up. This causes in awakened nights and sleepy mornings due to disrupted sleep patterns. Jet lag tends to worsen with age. Exposure to light is one of the powerful factors determining the circadian rhythm. Melatonin can be helpful in enhancing the adaption to new time zone, if appropriately timed. Jet lag is determined by various other factors such as the extent of difference of time zone, probable duration of stay at the new place, and direction of travel. In case of shorter duration of trips lasting <3 days, it is advisable to stay in sync with the time of origin country. In order to adapt to the destination time zone readily, it is advisable to move bed time and wake up time with respect to the destination time zone 3 days prior to the date of departure. However, this may not possible in practical situations. If possible, modification in sleeping and waking time can help one get acquainted with the new time zone better. Avoid consumption of sedative or hypnotic medication prior or during the journey. In some cases, it can be helpful to avoid early morning light and expose to late morning or afternoon light. At the destination, continue the same sleep wake pattern established prior to the journey. Set your clock on mobile phone to the new time zone.

INSURANCE OF TRAVEL

It covers medical, dental, and travel expenses; usually that are not covered in regular health or other insurance plans. Premium insurance plans range for 24 h/day for 7 days or during the period of stay, in the destination country. It connects the traveler to the best doctors available around their locality round the clock, in the event of emergencies or for aeromedical evacuation, if necessary. Frequent travelers can avail for yearly insurance plans or for individual trips as per their convenience. In most travel insurance policies, basic healthcare facilities are included. However, additional policies may be excluded. About 6–8 weeks prior to departure, travelers are recommended to review their current plan of insurance policy, check for options not available and payment options including credit card, debit card, or online transfer. Coverage for international travel must include medical care costs and aeromedical evacuation at least. Apart from these, dental care, personal liability, cancellation charges coverage, personal effects lost, and carrying body of relative after death. In some policies, even loss of income, relatives and family members' transportation, and daily allowance are included. Travel to war zones, certain infectious diseases, pregnancy, and travel for adventure sport activities are usually not included in insurance policies. It is always advisable to check with the insurance company to include other policies to ensure safe and insured travel to an unknown destination. In case of travelers above 60 years or age or existing premedical conditions, where insurance policies cannot be availed, it is advisable to study about bilateral government healthcare agreements. In case of worse case scenarios, at the least, arrangement to travel back to home country must be prepared.

Patients with ongoing medical treatment and chronic medical conditions should carry a detailed history of their condition, medication history and past history of surgery, and allergy history. This can be obtained from their healthcare personnel prior to departure. Their travel insurance agency number and emergency contact of family member or spouse should be mentioned in this document. It is advisable to carry the above documents in carryon luggage as it is helpful in case if the luggage goes missing. It is a hard and tedious job to obtain medications in a foreign land. Hence, it is advisable to take in to consideration the possibility of loss of medicines, articles of clothing, documents (medical or nonmedical), and money. One must be prepared beforehand in order to avoid mishaps during or after arrival at the destination.

SPECIFIC CONSIDERATIONS: HEALTHCARE PERSONNEL

Healthcare personnel (inclusive of practicing doctors, registered nurses, paramedical staff, cleaners, and sweepers) in contact with patient or relatives of patient are more likely to be infected with respiratory diseases through contact or droplet routes of transmission. The health and wellbeing of these healthcare workers are critical as they will be providing their care and medical help to the community they serving. In most developing countries, the access to clean and portable drinking water is scarce. It might be safe for people living in the locality since they develop resistance to the microbes due to long-standing exposure. Hence, new residents readily acquire these infections due to their low immunity status and resistance to these microorganisms.

For disinfection of water, use of iodine tablets or chlorine, commercial water filters, domestic appliance of water filters, or boiling water to 70°C (160°F) for 30 minutes. Solar radiation and UV filters are used to acquire clear water.

Use of Personalized Protective Equipment

Use of sterile gown/coverall suits, sterile glows, N95 mask or respirators, and knee length shoe covers should be encouraged in all cases. This enables the personal safety and protection of the treating doctor and nursing staff as well as prevents transmission of these contagious diseases to other patients and staff within the vicinity. Proper steps of handwashing before and after in contact with the patient must be practiced.

All healthcare personnel must take adequate precautionary steps in preventing any needlestick injuries to themselves or others around them. Vaccination for hepatitis B should be given to all doctors and staff as a precaution.

Postexposure Prophylaxis

In the event of contact of bodily fluids or needlestick injury from a HIV-positive patient, postexposure prophylaxis must be started at the earliest. Most commonly used regimen is tablet tenofovir 300 mg (one tablet) or tablet emtricitabine 200 mg once a day and tablet raltegravir 400 mg twice a day for up to 4 weeks.

SPORTS RECREATION

There are higher incidents of injuries and fatalities recorded with travelers during adventurous activities such as base jumping, water sports, snowboarding, sky diving, and alpine skiing. It is estimated that for every 60 participants for base jumping there is one fatality reported per year (1.75). The injuries rate for snowboarding is 6.1 incidents of injury/1,000 visits and 2.5 incidents of injury/1,000 visits for alpine skiing. However, it is a lower estimated risk but pose a higher degree of threat to serious injuries.

As a preventive measure, review with the company associated with the sport activity about the standard of safety equipment and ask for certification for authentication. Make sure all safety gears, harness belts, properly fitting helmets, and well-trained and certified staff are present at the time of activity. Proper medical evaluation before travelling is imperative and clearance of the same should be obtained to prevent any chances of syncope or collapse during the activity. Ensure that medical professionals are available in the nearest facility in case of an emergency. Make prior arrangements in the event of transporting any casualties or seriously injured patients to another location. The emphasis on certified and well-experienced guides is done to prevent the risks of morbidity or mortality, as it is observed that these injuries pertain to activities undertaken by individual groups with no proper certification or license as opposed to certified and licensed companies.

WATER ENVIRONMENT AND DIVING

Over the past 10 years, people traveling for water sport activities are exceedingly common, domestically and internationally. However, contrary to belief traumatic injuries are less frequent with water sports than with land-based activities. Water sport hazards may include collisions with equipment and land, drowning, failure of adequate oxygen supply, and submersion that pose a serious risk to life.

Scuba diving is most prevalent among water sport activities with drowning and decompression sickness being the most serious illness. It is advisable not to travel by air for 12–48 hours after diving. The degree of decompression sickness depends upon the length and depth of dives and the number of dives. However, the postdiving air travel can be avoided for initial 48 hours and after which it is best to consult for a medical evaluation before planning to return home.

Preparation for Water Related Environment/Water Sports

- *Exposure to sun*:
  - Apply sunscreen with high sun protection factor (SPF) and is water resistant.
  - Sunscreen must be applied prior to the application of DEET (containing insect repellent). If DEET is applied after sunscreen, it will decrease the time of effect of sunscreen.
- *Prevention of hypothermia*: Exposure to cold water–
  - Old aged individuals (>60 years) and children are more prone to hypothermia. Use of wet suits and dry suits is recommended. Make sure the exposure time is not unsupervised for a long period of time.
- *Seasickness*:
  - If a patient is known to have boat sickness, it is advisable to start the premedication prior to travel by boat in order to reduce the dizziness.
  - Sound knowledge about the hazardous marine life locally. Be aware of venomous and nonvenomous stings of marine life. Cover all exposed areas with appropriate wet suits. Always engage in water sport activities under the supervision of certified and licensed guide or company.
  - Avoid exposure to fresh water or stagnant water bodies to prevent infections of schistosomiasis and leptospirosis. Dry all areas of skin exposed to fresh water with fresh clean towel and apply DEET on skin.
  - For high-risk travelers, prophylaxis with tablet doxycycline 200 mg orally weekly can be started.
  - Exposure to brackish and salt water should be avoided. Proper and timely cleaning of wounds with antiseptic solution and clean dressing is recommended. If required, standard antibiotic regimen should be started at the earliest.
  - Make sure you are trained in swimming prior to undertaking any activities involving water bodies. Avoid consumption of alcohol during or prior to such activities. Check weather condition (high tides) around before the activity. Patient with high-risk conditions should undergo medical evaluation (cardiac disease and seizure disorders). Ensure that life preservers are present at all times during the water sport activity. Ensure the availability of pediatric-sized floating devices. If not present, carry your own.
  - Avoid musculocutaneous and soft tissue injuries by soft handling the equipment first. Prior study on instructions to use and handle them must be done to prevent injuries. One must acquaint themselves of first aid training, basic wound care, and management of minor cuts and bruises.

THROMBOSIS

Long hours of travel by air, usually >6 hours tends to draw a link between thrombosis and pulmonary embolism. This is due to immobilization of lower limbs while sitting for longer periods of time than usual. This can be risky for individuals with prior history of thrombotic events, post-coronary artery bypass grafting (CABG) status, and postorthopedic surgeries, obese individuals, or any healthy individual as well. Incidence of thrombotic events accounts for 1 in every 4,600 flights lasting >4 hours. Further, there is an increase in 18% for every flight lasting 6 hours or more. Passengers with risks mentioned above or other medical conditions are at higher risk.

Precautionary measures are undertaken like practicing foot and leg exercises every 2 hours to allow increased blood flow to the lower limbs. Adequate hydration throughout the

journey can be helpful in preventing any signs of dehydration. Use of compression stockings (15–30 mm Hg) for higher risk patients is recommended. However, some practitioners advise the use of low-molecular-weight heparin subcutaneously before departure and 24 hours after departure as prophylactic treatment for patients with previous history of thrombotic vents or thrombophilia. Aspirin is of no proven benefit as prophylaxis for passengers. Passengers may choose aisle seating option to allow more leg space for mobility of foot and leg.

ACUTE ALTITUDE ILLNESS

Acute altitude illness (AAL) is a consideration for all travelers ascending a height above 2,000 m (6,562).

Acute altitude illness comprises of:

- Acute mountain sickness (AMS)
- High-altitude cerebral edema (HACE)
- High-altitude pulmonary edema (HAPE)

Acute altitude illness is present in individuals ascending above 2,500 m (8,202) and 25% of travels that ascend rapidly. Prevention of acute altitude illness is to gradually ascend. In cases of high risk, prophylaxis treatment with tablet acetazolamide 125 mg twice daily for adults to be started 2 days prior to the ascend to 2,800 m or above and continue same treatment for 2 days beyond highest altitude attained. Pediatric dosage is 2.5 mg/kg/dose and can follow the same regimen as adults. In adults with sulfa allergies or those who cannot take acetazolamide, tablet dexamethasone 2 mg every 6 hours or 4 mg every 12 hours can be started 24 hours prior to the ascent and should be continued for 10 days.

TERRORISM/UNSTABLE POLITICAL SITUATIONS

Travel to countries involved in terrorist activities, ongoing war, famine, unstable political situations or with increased rates of violent crimes, rapes, murders, etc., can be very challenging and daunting. It is recommended to contact the embassy of your country in the country of destined travel about the magnitude of the situation. During the process of visa, make sure of arrangements made for a flight back to your home country in case of emergencies. While staying in hostile conditions, make sure to leave with a supply of medical kit and essentials in case of first aid or unavailability of medical help. Always try to make prior contacts of trustworthy local individuals who might offer help. However, one must look out for crooks and thieves during such conditions of instability. At the worst case, travel at times of uncertainty can be avoided until the situations in the destination are better or completely safe. In the end nothing is really important than assuring one's safety.

UPDATED WHO RECOMMENDATIONS FOR INTERNATIONAL TRAFFIC IN RELATION TO COVID-19 OUTBREAK

On 30 January 2020, the Director-General of the WHO, following the advice of the Emergency Committee convened under the International Health Regulations (2005), declared the current outbreak of COVID-19 a public health emergency of international concern and issued Temporary Recommendations. The committee asked the Director-General to provide further advice on these matters and, if necessary, to make new case-by-case recommendations, in view of this rapidly evolving situation. As of 27 February 2020, although China, particularly the Province of Hubei, has experienced sustained local transmission and has reported by far the largest number of confirmed cases since the beginning of the outbreak, lately the situation in China showed a significant decrease in cases. At the same time, an increasing number of countries, other than China, have reported cases, including through local transmission of COVID-19. As the epidemic evolves, it will be expected that many areas may detect imported cases and local transmission of COVID-19. *As of September 1, 2021 in total 32 million cases of COVID-19 have been reported from India meanwhile, worldwide total 220 million COVID-19 cases and 4.5 million deaths have been reported.*

Recommendations for International Travel during Ongoing Transmission

With the contamination of new patients on daily basis worldwide, it is not advisable to countries with more number of affected cases than your maiden country. While travelling internationally, healthy individuals may come in contact with sick or COVID-19 positive patients at airports, airplane, ships, trains, or buses. This may either lead to development of symptoms in the new patient or a carrier state. A carrier status in a passenger will be asymptomatic and may travel back home and further transmit the COVID-19 virus to other members of family. Recent studies of cases, both old or new, it is imperative that this disease is more serious and life-threatening to older individuals above 60 years of age, underlying medical conditions (diabetes mellitus, cardiac conditions, chronic renal diseases, and previous history of respiratory conditions: Pneumonia and interstitial lung disease), pregnant mothers, young infants, and immunosuppressed patients with chemotherapy ongoing. Healthcare institutions are becoming overburdened in developing countries like India, where the doctor to patient ratio is 1:1,800, in contrast to the WHO guidelines for recommended minimum doctor to patient ratio of 1:1,000. This limits the availability of medical attention to few individuals, leaving the majority of population helpless. With the rise in number of positive cases rising on a daily basis, many countries have restricted travel from highly affected countries to prevent increase in cross contamination. Primarily individual travelers will be screened for fever at evaluation, cough and cold, and sudden onset breathlessness at the entry point in airports.

Recommendations for International Travelers

Maintain adequate hand hygiene: Precaution is better than cure. With no definitive cure in the current situation and only supportive therapy, it is advisable for all travelers domestically or internationally to clean their hands with an alcohol-based sanitizer (at least 60% alcohol). If possible, it is recommended to wash their hands for 20 seconds for it to be effective. During the journey, always wear gloves and avoid touching your face, mouth, or nose.

Keep distance of 6 feet apart from contact for others. Social distancing should be maintained at all times prior to departure and during the time in the airport. Social distancing means staying out of crowded places, avoiding group gatherings, and

maintaining distance (approximately 6 feet or 2 meters) from others when possible.

Wear a N95 mask, surgical mask (3 Ply), or cloth-based mask to cover the nose and mouth.

While coughing or sneezing, raise your elbow to your face in order to cover your face and mouth. This will prevent spread to others in close proximity.

It is advisable not to travel under such times of crises and global pandemic if you are sick.

After reaching the destination, initial screening at the airport is done. After arriving in India, all international passengers would be quarantined at home or a hotel facility away from their family or friends. They are counseled about the need of informing designated authorities in case of development of symptoms.

In case of active symptoms mentioned above after travel internationally, the passenger is asked to be tested at the earliest. If he/she is stable, they are asked to stay at home quarantined for 14 days or admitted to a healthcare facility for further medical attention.

SUMMARY

In most of the situations, travelers across the globe underestimate the health and safety risks involved. In very few cases, an international traveler seeks consultation about proper travel counseling prior to the date of departure. Pretravel counseling includes individual approach on risk assessment, immunization schedule reviewed, details of arthropod-related diseases and protective measures, prophylaxis for malaria, and traveler's diarrhea along with risk reducing measures and travel-related education. This serves to be a helpful aid to a person travelling to developing countries, for adventure sports or activities, extended travel plan, travelling with a chronic medical condition or immune-compromised state, and travelling with children or pregnant mothers. It is ideal to undertake a medical consultation at around 6 weeks before the date of departure. Travelers should consider to carry travel medical kit (**Table 4**) along with them. In view of the recent COVID-19 pandemic, advisory by the WHO needs to follow.

TABLE 4: Travel medical kit.

Personal health documentation: • Allergy list • Current medications • Immunization record • Medical/Surgical history with list of diagnoses • Emergency contact information • Medical insurance information • Any prescription medicines	*Allergy:* • Epinephrine autoinjector (0.3 mg) • Short-acting antihistamine: Diphenhydramine 25 mg and meclizine 25 mg • Long-acting antihistamine: Cetirizine 10 mg, loratadine 10 mg, and fexofenadine 180 mg • Scopolamine patch 1.5 mg
Altitude illness: • Acetazolamide 125 mg • Dexamethasone 4 mg • Nifedipine 30 mg *Antiemetic:* • Ondansetron 4–8 mg oral dissolvable tablet • Promethazine 25 mg rectal suppositories	*Antibiotics:* • Amoxicillin 500 mg • Ciprofloxacin 500 mg • Azithromycin 250 mg • Trimethoprim/Sulfamethoxazole 160/800 mg • Cephalexin 500 mg • Amoxicillin/Clavulanate potassium 875/125 mg • Nitrofurantoin 100 mg
Antifungal: • Fluconazole 150 mg • Miconazole 2% cream • Clotrimazole 1% cream • Ketoconazole 2% cream *Antiviral:* • Oseltamivir 75 mg	*Antimalarial:* • Chloroquine 500 mg salt (300 mg base) • Mefloquine 250 mg salt (228 mg base) • Atovaquone-proguanil 250/100 mg • Arthropod avoidance • DEET 20–50% • Picaridin 20% • Permethrin 0.5% solution
Emergency contraception: • Levonorgestrel (Plan B One-Step) 1.5 mg • Ulipristal (Ella) 30 mg	*Eye care:* • Saline drops • Contact lens holder and spare glasses/contacts • Polymyxin B sulfate/trimethoprim ophthalmic drops • Erythromycin ophthalmic ointment

Continued

Continued

Gastrointestinal: • ORS • Bismuth subsalicylate 262 mg • Loperamide 2 mg • Calcium carbonate 500 mg • Ranitidine 150 mg and omeprazole 20 mg • Calcium polycarbophil (FiberCon) 625 mg • Docusate sodium 100 mg	*Pain/Antipyretic:* • Acetaminophen 500 mg and ibuprofen 400 mg • Postexposure prophylaxis • Tenofovir 300 mg/emtricitabine 200 mg • Raltegravir 400 mg
Respiratory: • Nasal saline drops • Pseudoephedrine 60 mg • Albuterol metered dose inhaler	*Skin:* • Hydrocortisone 1% and triamcinolone 0.1% • Mupirocin ointment sunscreen • N-acetyl-5-methoxytryptamine (melatonin) 0.5–5 mg • Sleep aid zolpidem 5–10 mg
First aid supplies: • Commercial first aid kit • Adhesive strips (Steri-Strips) • Adhesive tape (Duct tape) • Alcohol wipes, antiseptic cleanser, and hand sanitizer • Band aids and dental kit • Disposable gloves • Elastic bandages and gauze (hemostatic gauze) • Local anesthetic • Moleskin/Molefoam	*Personal protective equipment:* • Safety pins • Scissors • Splint • Suture kit/sutures/stapler • Syringe/Needle • Thermometer • Tweezers • Wound glue

(DEET: diethyltoluamide; ORS: oral rehydration salts)

CHAPTER

In-flight Medical Emergencies

Devendra Richhariya

INTRODUCTION

A large number of people are travelling aboard through commercial airlines every year and in-flight medical emergencies are also increasing worldwide each year. A medical professional may get a sudden call for assistance in the unfamiliar surroundings of an airliner cabin. Medical professional who is experienced in "wilderness medicine" requires to adopt improvisational approach to address the medical issues. Physicians who are travelling in commercial flight need to assist the passenger who is having a medical emergency and most of them need hospitalization as well. So physician should be aware about the common in flight medical emergencies and their management in unique environment and the liabilities, they may incur when offering assistance. No mandatory reporting system exists in estimating the frequency of in-flight medical events is challenging because so this is likely to be an underestimated. This chapter briefly discusses on the unique conditions, challenges, and constraints of the flight environment and resource management to equipment required.

THE FLIGHT ENVIRONMENT, CABIN ALTITUDE, AND CABIN AIR

Modern commercial aircrafts roughly fly at equivalent to a cruising altitude of 32,000–45,000 feet between the troposphere and stratosphere. Panes fly more smoothly and experience less turbulence above the troposphere. Pressurized cabin of the aircraft protects the passengers from high-altitude atmospheric conditions by creating its own medical ramifications.

The ambient atmospheric pressure is roughly 0.2–0.3 ATM at cruising altitude (30,000–40,000 feet). The cabin must be pressurized for survival of patient and to operate in this environment. Typically pressure between 6,000 and 8,000 feet above sea level is maintained in the cabin of the aircraft. Maintaining the cabin pressure at sea level is difficult to maintain would make the plane unacceptably heavy and expensive to build and operate. So, preventing passengers from becoming hypoxic in aircraft, compromise is made that is the most efficient for weight/strength/expense. Newer aircraft can pressurize the cabin to lower altitudes, equal to about 6,000 feet, and even in the upper flight levels. The fractional oxygen content of the air in the cabin is the same as that at sea level, approximately 21%. Atmospheric pressure changes with increasing cabin altitude. At a typical cruising altitude, the atmospheric pressure in the cabin is decreased by about 25–30% and results in a similar decrease in the partial pressure of inspired oxygen. Slight hypoxemia, with a corresponding decrease in oxygen saturation and a mild compensatory hyperventilation and tachycardia may occur in a traveler because of lower partial pressure of oxygen in the aircraft cabin results. Physician, who is attending the inflight medical emergencies, should be aware of physiologic changes like decreases in arterial oxygen saturation in the range of 3–5%, even in healthy individuals.

The risk of getting infection during a commercial flight arises from the close proximity to potentially infected passengers, and not from the quality of air in the cabin. A crowded airplane has similar risk of getting infection than other enclosed spaces. About 40–50% portion of the cabin air is recirculated and passes through high-efficiency particulate air filters and 94% and 99.9% of all airborne microbes are filtered during this process.

Low Humidity of Cabin Air

Typical humidity levels in most airliners are about 2% and airline cabin is usually dry. Airplane designers are happy to minimize moisture to help inhibit structural corrosion. Maintaining optimal cabin humidity (40–70%) is prohibitive because of the increased cost and weight of equipment. Low cabin humidity levels can lead to dehydration, so passengers are encouraged to increase water intake. Dry eyes may occur in patient with preexisting eye problem, and soft contact lens wearers so carrying "artificial tears" is beneficial. Dry-inflamed upper respiratory mucosa can produce cough and exacerbate reactive airway disease.

PRESSURE AND DYSBARISM

Middle Ear

Reduction in aircraft cabin pressure can lead to volume expansion of closed gas containing compartments in the

human body. Symptoms develop due to expanding volumes of air in the paranasal and frontal sinuses, but the most common manifestation of dysbarism is barotitis media resulting in to ear pain. Risk factors for barotitis media are associated with to eustachian tube congestion secondary to upper respiratory infections, middle ear infections, chronic effusions, or allergies. Mild barotrauma may occur as the aircraft ascends (increase in pressure and expansion of gases) or with descends of aircraft (decreased pressure in the middle ear). Mostly mild discomfort in ear is the typical presentation, in rare cases, rupture of the tympanic membrane may also occur with change in pressure. Swallowing (chewing gum or sucking on hard candy) is the simplest and commonly used method to open the eustachian tube. During descent, infants should be given a bottle or pacifier to suck on to facilitate swallowing. Older children and adults may benefit from performing a Valsalva maneuver. This is performed by pinching the nostrils and attempting exhalation through the nose. This maneuver is familiar to most scuba divers, because the same technique is used for equalizing ears during descent. Another useful technique is attempt swallowing while pinching the nostrils closed. Various pressure equalization techniques are helpful:

- *Voluntary tubal opening*: Traveler can attempt to yawn or by wiggling the jaw.
- *Valsalva maneuver*: Gently blow through your nose after pinching the nostril.
- *Toynbee maneuver*: Swallow (good technique during ascent) after pinching the nostrils.
- *Lowry technique*: Pinch your nostrils, and gently try to blow air out of your nose while swallowing.

Dental

Patients with preexisting dental disease such as a dental abscess (barodontalgia) may experience toothaches due to changes in cabin pressure.

Abdomen

Travelers may experience abdominal discomfort due to intraluminal gas expansion caused by decreased cabin pressure. Complications may occur during flight subsequent to recent abdominal surgery and surgical ligature. Surgeon's advice should be taken before planning the air travel. Travelling should be avoided for 10 days after abdominal surgery. It is advisable to avoid travel by air for 24 hours after colonoscopy, where a large amount of gas has been introduced into the colon, after laparoscopic intervention and neurosurgical intervention. It may be necessary to delay travel for approximately 2 weeks after ophthalmologic procedures for retinal detachment involve the introduction of gas by intraocular injections, which temporarily increase intraocular pressure.

Gas Expansion and Medical Devices

Fixed quantities of air are used in various medical devices include pneumatic splints (air splints), feeding tubes, urinary catheters, cuffed endotracheal tubes, and cuffed tracheostomy tubes. During rapid ascent in unpressurized and pressurized aircraft, trapped gas within these devices expands and known to cause barotrauma. During flight, air can be replaced with water in these devices to eliminate the effects of gas expansion, if not contraindicated. These devices need careful monitoring during air travel; cuff should be partial deflated if overexpansion is suspected. Caps of feeding and infusion tubes should be opened.

Pneumothorax

As air expands within the pleural space during ascent, patient with a small, asymptomatic pneumothorax can develop in to more significant pneumothorax. Risk of flight-related pneumothorax during air travel is increased in patients with preexisting pulmonary disease, cystic lung disease, recent pneumothorax, thoracic surgery, and chronic pneumothorax.

ON-BOARD MEDICAL RESOURCES

Airlines carry first-aid kits to assist medical emergency providers. First-aid kits consist of basic supplies such as bandages and splints, additional items are listed in **Table 1** and should have at least one automated external defibrillator (AED). Airlines usually contract with ground-based medical consultation services because health professionals are not aboard in every flight. Patient at these centers can get treatment recommendations by specialist. During emergency, on-board volunteer providers can also consult these services. Flight attendants should receive cardiopulmonary resuscitation (CPR) and the use of AEDs training every other year.

AUTOMATED EXTERNAL DEFIBRILLATORS

If there is a cardiac arrest on-board, and if one considers the 20–30 minutes required for an emergency landing from cruising altitude, plus a 10-minute taxi time to the gate, it is clear that these patients rarely survived. The successful introduction of AEDs for outside hospitals use has successfully improved survival rates after ventricular fibrillation. On these bases, airline organizations introduced AEDs into their aircraft fleet. If an AED is on-board, typically at least one cabin crew member should be trained in its use. Airlines allow only crewmember to manage the AED and cabin crew may assist or direct its use. If CPR is indicated, CPR can be started and cabin crew (trained in basic CPR) to assist. Modern AEDs may have electrocardiographic display (monitor) that shows the cardiac rhythm. AEDs with monitoring allow better decision-making when a passenger presents with chest pain, palpitations, dyspnea, or light-headedness. Recent modern equipment can monitor blood pressure, tympanic temperature, glucometer, oxygen saturation as measured by pulse oximetry, respiration and breath gas analysis, and electrocardiogram, and transmit these data to a remote physician for diagnosis. The device allows monitoring of electrocardiogram when used in conjunction with a smart phone.

Limitations of In-flight Automated External Defibrillators

Limitations of in-flight AEDs include the following—Inability to deliver the shocks because of patient movements interfering with analysis; prematurely turning off the AED, not able to follow instructions to deliver shocks, AED leads are off; misreading the AED screen instruction to start CPR; and inflight vibration may interfere in operating the AED even for trained healthcare professionals. Some airlines only allow cabin crew who is trained in CPR to operate on-board AEDs.

TABLE 1: On-board emergency medical kits.

Content	*Quantity*
Sphygmomanometer	1
Stethoscope	1
Airways, oropharyngeal (3 sizes): 1 pediatric, 1 small adult, 1 large adult or equivalent	3
Self-inflating manual resuscitation device with 3 masks (1 pediatric, 1 small adult, 1 large adult or equivalent)	3
Cardiopulmonary resuscitation mask (3 sizes): 1 pediatric, 1 small adult, 1 large adult or equivalent	3
IV administration set: Tubing with 2 Y-connectors	1
Alcohol sponges	2
Adhesive tape, 1-inch standard roll adhesive	1
Tape scissors	1
Tourniquet	1
Saline solution, 500 mL	1
Protective nonpermeable gloves or equivalent	1 pair
Needles (2–18 gauge, 2–20 gauge, 2–22 gauge, or sizes necessary to administer required medications)	6
Syringes (1–5 mL, 2–10 mL, or sizes necessary to administer required medications)	4
Analgesic, nonnarcotic, 325-mg tablets	4
Antihistamine, 25-mg tablets	4
Antihistamine injectable, 50 mg (single-dose ampule or equivalent)	2
Atropine, 0.5 mg, 5 mL (single-dose ampule or equivalent)	2
Aspirin tablets, 325 mg	4
Bronchodilator, inhaled (metered dose inhaler or equivalent)	1
Dextrose, 50%/50 mL, injectable (single-dose ampule or equivalent)	1
Epinephrine 1:1000, 1 mL, injectable (single-dose ampule or equivalent)	2
Epinephrine 1:10,000, 2 mL, injectable (single-dose ampule or equivalent)	2
Lidocaine, 5 mL, 20 mg/mL, injectable (single-dose ampule or equivalent)	2
Nitroglycerine tablets, 0.4 mg	10
Basic instructions for use of the drugs in the kit	1

ON-BOARD MEDICAL OXYGEN (PORTABLE OXYGEN BOTTLES)

Most of the airlines carry a minimum of one portable oxygen bottle (POB) per flight to fulfill the minimum oxygen requirement.

Flow Rates and Duration

If called to assist in an on-board emergency, keep in mind that POBs may have only two fixed settings—(1) high (4 L/min) and (2) low (2 L/min) constant flow. Selection is made via a knob mounted on top of the regulator. Alternatively, some airline POBs are adjustable between 2 and 8 L/min.

Personal Portable Oxygen Bottles

Portable oxygen bottles are considered as hazardous material as they contain compressed gas or liquid oxygen that so airlines prohibit the use. Airlines are allowed to carry a passenger's filled oxygen cylinder in the aircraft cabin but the passenger cannot use it. However, because of various requirements like written pilot notification, additional HAZMAT training, and manual documentation, most airlines do not offer this service. Passengers, who are planning to carry their own oxygen cylinder on-board for use, should check with the specific airline before travel because liquid oxygen is classified as a hazardous material. Passengers who are on continuous medical oxygen are either not allowed to travel, or may request, to submit "fit to fly" certificate from a licensed physician, that they can complete their flight without the use of medical oxygen.

Carrier-Supplied (Compressed) Oxygen (Portable Oxygen Bottles)

Passengers who need oxygen therapy during flight, they may contact the airline as some airlines provide, for a fee, compressed bottled oxygen during flight. Flow rates and available equipment, such as masks vary with airlines. And airlines do not provide oxygen for passengers before or after a flight (e.g., between connecting flights).

Personal Portable Oxygen Concentrator

Check with the specific airline to see if they allow portable oxygen concentrator (POC) devices to be brought onboard and for use during flight. Passengers can use *personal* POCs during long layovers or delays.

Continuous Positive Airway Pressure Devices

Continuous positive airway pressure devices are the requirement for patients with sleep apnea during long-duration flights. Most domestic and international flights permit portable continuous positive airway pressure devices because these devices are classified as "medical assist devices".

SPECIFIC MEDICAL CONDITIONS

Cardiac Arrest

Managing the cardiac arrest among all in-flight medical emergencies is challenging in the setting of an aircraft cabin, due to confined and restricted space for patient care and less than appropriate positioning of the patient, limited personnel with the appropriate skill set, and few supplies the potential interventions are limited. During flight, only basic approach is the most appropriate and only possible approach for the management of cardiac arrest. So inflight management of cardiac arrest by volunteer physician should consist of cardiac arrest recognition, compression-only CPR, and defibrillation with the use of an AED. If return of spontaneous circulation (ROSC) is achieved during resuscitation, diversion and

emergency landing are probably the most appropriate recommendations, if diversion is not immediately possible, the volunteer physician should continue best possible care and monitoring of the patient. Consider cessation of resuscitation efforts and pronouncement of death if a ROSC is not achieved within 20–30 minutes. If the patient does not have a favorable response, justify discontinuing of resuscitation particularly in austere environment of aircraft cabin. A shockable rhythm may prompt the clinician to continue resuscitation. Only a physician is allowed to pronounced death during flight.

Acute Coronary Syndromes

Chest discomfort, dyspnea, nausea, vomiting, and diaphoresis are the common symptoms of acute coronary syndrome. Other manifestations include syncope or presyncope, respiratory symptoms, and cardiac arrest. There are very limited management options for a suspected acute coronary syndrome in an in-flight patient. Aspirin is recommended in most adult patients with chest pain who are suspected of having an acute coronary syndrome; active, clinically significant hemorrhage, and a true allergic reaction the only absolute contraindications to administration of aspirin. Sublingual tablets of nitroglycerine present in the medical kits, and should be used with caution. In certain situations, nitroglycerine can cause or exacerbate hypotension and shock such as in acute inferior ST-segment elevation myocardial infarction with right ventricular infarction (a diagnosis that cannot be made on a commercial aircraft in flight). In an ill looking patient, intravenous access should be achieved; fluid bolus may be helpful in patients with hypotension. Supplemental oxygen should be started and the clinician can request a descent to a lower altitude to improve oxygenation if patient saturation is low. A patient who is in an unstable condition (sick looking), should prompt a possible acute myocardial infarction and recommendation to the crew for immediate diversion. A patient at lower risk for an acute coronary syndrome, in stable condition, should prompt a less urgent recommendation for diversion; the patient should be offered transfer to a hospital by emergency medical-service personnel on landing.

Stroke

Acute stroke can present in various ways. A passenger, who has an abrupt onset of neurologic symptoms, should be considered as potential diagnosis of acute stroke. Patient should be evaluated for focal neurologic deficits because performing a complete neurologic assessment is challenging in the confined environment of an aircraft. Suspected strokes as an in-flight medical emergency with evidence of respiratory compromise should consider providing supplemental oxygen, because neural cells must be protected from further hypoxemia injury. In view of limited available oxygen supply, use the lowest necessary flow rate. Aspirin is available in the emergency medical kit, but should not be given in flight for a suspected stroke because possibility of an intracranial. The blood sugar level should be measured, if possible because strokes can also be mimicked by hypoglycemia. Although some airlines carry glucometer as part of an emergency medical kit. If glucometer is not as part of the medical kit, healthcare providers can borrow from other passengers; the cleanliness of the device is utmost important to prevent the transmission of bloodborne pathogens. Finally, healthcare provider should recommend a landing on suspicion of an acute stroke.

Altered Mental Status

Various underlying neurologic conditions may be exacerbated during air travel and may cause altered mentation. The physician assisting such a passenger must be aware of a wide differential diagnosis such as metabolic derangement, infection, vascular pathology, intoxication, trauma, hypoxemia, and postictal states. Seizure thresholds are also potentially lowered by in-flight hypoxemia. Reversible causes of a patient's altered mentation (hypoglycemia, hypoxia) must be assessed and rectified by clinicians. The blood sugar level should be assessed and corrected by oral blood glucose or intravenous dextrose. Hypoxemia should be corrected by supplemental oxygen and the descent to a lower altitude should be requested. Altered mental status may be debilitating or fatal, so recommending an expedited landing or diversion is advisable.

Syncope

Out of all aircraft medical emergencies, syncope and presyncope are relatively common medical events; many passengers are somewhat dehydrated as passenger aircraft cabins are pressurized by air pumped through the engines, which results in a relatively dry environment. Other contributing factors like altered eating patterns, fatigue from delayed flights may also cause syncope. Passenger's blood pressure and pulse should be measured by attending physician because intravascular volume depletion or bradycardia can readily cause syncope or presyncope. Keeping the patient on the floor with the feet elevated may provide rapid relief. Intravenous fluids should be given in patients with persistent hypotension. The blood glucose level and oxygen saturation should be checked. Underlying medical conditions of the patient should be assessed, some of which may be potentially fatal. Passengers who have persistent symptoms or abnormal physical findings, especially in elderly passengers with serious cardiac disease the responding physician should consider recommending a diversion because these patients are at increased risk for death.

Trauma

Usually, minor trauma is a relatively common on commercial airlines, mostly resulting from blunt force trauma due to turbulence. Mostly these are nonlethal injuries, but specific factors such as age, medical conditions, and use of anticoagulants must be considered while evaluating the injury. Basic first aid, cold compresses, and analgesia are required for most of the traumatic injuries. If a fracture or dislocation is suspected, the patient should be placed in a nonweight-bearing position with appropriate splinting. A thorough history and a physical examination should be performed in head trauma even if it is minor. Frequent reassessment of injury helps in early recognition of severe injury and recommendation of expedited landing or diversion.

Dyspnea

Underlying respiratory diseases of the passengers can be exacerbated due to reduced oxygenation in aircraft cabin. Acute exacerbations of chronic obstructive pulmonary disease, severe hypoxemia in patients with pulmonary hypertension can occur as a plane gains altitude. Supplemental oxygen should be started in passengers with dyspnea. Permission to travel with additional oxygen should be provided to passengers with respiratory illnesses and a resting oxygen saturation <92%. Bronchospasm should be treated with albuterol metered-dose inhaler available in the medical kit. Clinician need to perform a needle thoracostomy using the on-board equipment on suspicion of pneumothorax in a patient who is in unstable condition. Descending to a lower altitude may also be beneficial, because cabin pressure is inversely proportional to the altitude of the aircraft.

Infectious Disease and Air Travel

Air travelers are subjected to long periods in enclosed spaces, which facilitate the spread of infectious disease in spite of clean cabin air, provided by modern airliners. Recently world is witnessing SARS-CoV-2 pandemic and learning about air travel with precaution, e.g., mask, social distancing, hand sanitization, personal protective equipment, and various outbreaks of serious infectious diseases have been also reported aboard commercial airlines including influenza, food poisoning, measles, tuberculosis, viral enteritis, severe acute respiratory syndrome, and smallpox. The risk of cross-infection from airborne pathogens in aircraft cabins increases with the longer duration of the flight (with 8 or more hours increases the risk) and proximity to infected passenger (seating within two rows associated with an increased risk). Ask the ill passenger to use a facemask, if a contagious disease is suspected. Medical kit and/or the first aid kit should have the mask and gloves. If a potentially contagious disease is suspected, the clinician should make an effort to isolate the patient and relocate neighboring passengers. Use of a facemask by the ill passenger, preventing them from moving around the cabin and relocation of neighboring passengers are the important measures, can reduce the risk of transmission. Discuss quarantining the passenger with the flight crew and any reporting requirements. When an acute infection is suspected performing compression-only CPR, isolation of body fluids should also be done. Potential quarantine and government reporting requirements also arise when a communicable disease is suspected and clinician should have a discussion with both ground-based medical services and the flight crew about.

Psychiatric Emergencies

Multiple stress factors such as lengthy check-in process, enhanced security measures, delayed flights, cramped cabins, and alcohol consumption may be responsible for in-flight medical psychiatric emergencies. Acutely agitated passengers pose safety concerns for other travelers, improvised physical restraints might be necessary to ensure the safety of other passengers (medical kit does not contain sedatives), physician must rule out any organic cause such as hypoglycemia. Various factors during air travel, which increase the emotional and physical stress, are the following—time pressures of travel, congestion in airport, cope up with connecting flights, stress and anxiety related to business travel, family related events, disruptions in circadian rhythms, lack of sleep and dehydration, and stress and anxiety associated with missed and cancelled flights.

Postdive (Scuba Diving) Air Travel

According recent studies, flying in a commercial aircraft even after a 24-hour in surface can produce bubbles in a diver's blood; Divers Alert Network advises for a 24-hour surface interval before flight.

Circadian Rhythm Sleep Disorder (Jet Lag)

Jet lag is a sleep disorder, develops in passengers who travel across three or more time zones. Jet lag occurs when the internal circadian rhythm "clock" adjusts slowly to the destination time. This disruption causes circadian rhythms to become out of synchronization with the destination time zone. The sleep-wake cycle is regulated by pineal gland by secreting melatonin. The melatonin synthesis and release is stimulated by darkness and suppressed by light. Symptoms of jet lag include poor sleep, sleep-onset insomnia, fraction of sleep, and early awakening; fatigue; mood changes; headache; irritability; poor concentration; depression; and mild anorexia.

Travelers can minimize jet lag by doing the following before travel: Shift the timing of sleep to 1–2 hours later for a few days before traveling westward. Shift the timing of sleep to 1–2 hours earlier for a few days before traveling eastward. If traveling westward, seek exposure to bright light in the evening, if traveling eastward seeks exposure to bright light in the morning. Rooster and Entrain, mobile apps are available to calculate and adhere to a light/dark schedule to help travelers to avoid jet lag.

For preventing jet lag, the use of the nutritional supplement melatonin (0.5–5.0 mg of melatonin during the first few days of travel) is controversial. Ramelteon, newer melatonin receptor agonists, recently has been approved for the treatment of insomnia, but has not been well studied for use in jet lag. Nonaddictive sedative hypnotics (nonbenzodiazepines), such as zolpidem, may be used to promote longer periods of high-quality sleep. Temazepam (short-acting benzodiazepine) is recommended to minimize over sedation. Caffeine in limited quantities promotes daytime alertness. Take short period of sleeps (20–30 minutes), shower, and spend time in the afternoon sun.

APPROACH TO PATIENT CARE DURING IN-FLIGHT EMERGENCIES

It is a challenge for the medical professional to assist someone in an isolated environment and without availability of specialized equipment. Responding physician can create a less stressful environment for the patient, crew, and other airline passengers by showing calm, competent, and professionalism. Licensed medical professionals, currently practicing medical provider only should respond to a call, should be ready to show a medical license that verifies your

training. It is appropriate to ask the patient for consent (if they are not altered) with a crewmember as witness before starting in-flight care. Ensure one flight attendant continues to assist responding physician assisting throughout the in-flight emergency, to maintain continuity and ensures that you have access to needed equipment and cockpit communications. Most of international flights have access to a ground-based consultant that is very helpful for any in-flight medical volunteer, if the passenger seems very sick, request the cabin crew to arrange ground-based consultation. If you have been drinking alcohol, do not respond or no other provider responds, make full disclosure to the flight crew and the patient. International airlines are not considered to be a covered entity regarding healthcare privacy, responding physician legally speaks to the flight crew about the medical issues of the sick passenger. Because of language barriers, history taking may be difficult, family members or another available passenger may act as an interpreter, request can be made via a simple cabin announcement. Obtain and record vital signs early in the event and focused physical examination is preferred because of limitations in space, vibration, and ambient cabin noise. Virtually, it is not possible to auscultate heart, lungs, or abdomen, patient should be moved to a larger area if a full resuscitation is indicated. You may be able to find additional medical equipment from other passengers, and do not hesitate to ask for additional help. Avoid performing procedures, if physician is unfamiliar with or announcement can be made for a nurse or emergency medical technician if physician out of practice, starting IV lines. Notify to the cabin crew, if the patient's presentation suggests a communicable disease. Despite the do-not-resuscitate order, the cabin crew may decide to continue resuscitation, if their company policy requires.

Cockpit Coordination

During management of the medical emergency, pilot in command or captain takes over the cockpit, copilot or "first officer" takes over the responsibility of flying the aircraft. Notification about medical emergency to air traffic controllers is given by nonflying pilot. Pilot/captain in consultation with a ground-based consultant always makes the decision to divert. Diversion is a complicated decision that must take into consideration factors such as fuel, costs, the ability of the aircraft to land at the closest airport, and the medical resources available at that airport. The most common reasons for diversion are cardiac, respiratory, and neurologic emergencies including nonrevolving chest pain, shortness of breath, severe abdominal pain, stroke persistent unresponsiveness, refractory seizures, and severe agitation.

Legal Ramifications

A medical responder who gives assistance develops a doctor–patient relationship, with its attendant obligations and liability risk. Law of that country determines the liabilities in which the aircraft is registered, but the law of the country in which the incident occurs or in which the parties are citizens could arguably apply. Provider should document all the events of the care and treatment given to the patient, should use airline-specific documentation as required. Providers should be careful about the patient's privacy rights and should not discuss the patient's care with third parties (e.g., media) without appropriate authorization from the patient. Provide all necessary medical management information to captain and cabin crew. The airline, considered to be a covered entity itself, is not obligated to follow regulations regarding healthcare privacy. It should be noted that all communications with medical ground consultants are recorded.

DEATH ON BOARD

International Air Transport Association Guidelines for death on board (January 2016) state that cabin crew trained to perform CPR, should continue CPR until one of the following occurs—(1) spontaneous breathing and circulation resume; (2) it becomes unsafe to continue CPR (e.g., heavy turbulence and/or forecasted difficult landing after liaising with the flight deck); (3) all rescuers are too exhausted to continue; or (4) the aircraft has landed and care is transferred to emergency medical service (EMS); airlines may choose to cease resuscitation and person is presumed dead if CPR has been continued for 30 minutes or longer with no signs of life, and no shocks advised by an AED. It may be advisable to avoid declaring death on board because the legal implications of declaration of death vary from country to country. Therefore, limit involvement to advising the cabin crew regarding the presumption of death.

FUTURE CHALLENGES

Challenges to be addressed in the future include the following—lack of standardization of the onboard medical care; lack of mandatory and standardized reporting system for a better understanding of the overall incidence of in-flight emergencies; lack of postflight follow-up to ascertain frequency of nonemergency medical issues (i.e., venous thromboembolism); and requirement of flight attendants to undergo training in AED and CPR every 24 months. Most airlines lack clear standardized medical protocols for flight attendants managing in-flight medical emergencies, including protocols for flight attendants on flights where no medical professionals are available to volunteer. Most of the airlines remain out of reach of modern telemedicine technologies despite recent advances in this field.

SUMMARY

In-flight medical emergencies are relatively frequent. Air travel can exacerbate the underlying diseases in passengers or new medical problem may arise during flight. Physicians should be prepared to provide care while traveling especially in medically austere environment. Physician must be aware of associated liabilities surrounding the delivery of in-flight medical care.

Occupational and Industrial Health

250
CHAPTER

Devendra Richhariya

INTRODUCTION: A GLOBAL VIEW ON OCCUPATIONAL HEALTH

Occupational health (OH) problems are a substantial global burden. All fatal and nonfatal work-related injuries and illnesses cause economic burden with loss of 4% of all work-years globally, equivalent to a cost of approximately 3,000 billion US $ for low-, middle-, and high-income countries. This is roughly equivalent to 4% of the global Gross Domestic Product (GDP) worldwide. One of the biggest public health achievements in the 20th century is improvements in OH and safety with decreases in fatal occupational injuries, improvements in mining safety, successful vaccination against hepatitis B, reductions in communicable diseases, and many more advances can be added to the OH community's tally. Regular follow-up and continued vigilance is necessary even if old problems have disappeared. High quality OH interventions are required in view of newer health problems related to musculoskeletal and psychosocial problems, ageing workforce.

There are three major challenges related to health and safety at work challenges:

1. To improve implementation of existing health and safety rules.
2. To improve the prevention of work-related diseases by tackling new and emerging risks without neglecting existing risks.
3. To take account of the ageing of workforce.

Occupational health is an even more emerging issue. Fatal accidents are higher, great efforts must be made for the reduction of recognized occupational and work-related diseases by enforcing OH standards and legislation, limiting exposure to both new and known health hazards such as silicosis, asbestosis, lead toxicity, or pesticide poisoning. The majority of these diseases, injuries, and accidents are preventable and emphasis is given on the enormous potential of OH programs. These programs are important, not only for the health, safety, and well-being of the global working population, but also for employers. Improving health at the workplace can result in reduced absences from work, can increase economic productivity and competitiveness of its staff, can reduce insurance premiums or medical costs, and can yield a range of intangible gains such as improved company profiles and worker engagement.

VALUE OF OCCUPATIONAL HEALTH FOR ALL STAKEHOLDERS

A whole range of stakeholders—workers, worker's families, healthcare systems, insurance companies, businesses and shareholders, customers, and even other companies, are benefited by improving OH at work since all of these parties avoid costs when work accidents or diseases are prevented. Three main stakeholders: employees, employers, and society are the most important beneficiaries of investing in OH. Some of these benefits are seen immediately such as fines from legal violations and compensation of occupational diseases, while benefits which give delayed but sustainable results are workers' health gains, corporate image, and increase in worker productivity (**Fig. 1**).

Employee

It is important to protect and promote the health of employees during and beyond working life as most of the world's population (58%) spend one-third of their adult life at work. OH interventions help in preventing the accidents or injuries at work, the prevention or early detection of diseases, and the health benefits from return-to-work. Various programs for lifestyle changes and health promotion activities at work, e.g., smoking cessation programs and reduced alcohol consumption by professional drivers, help in creating a good healthy environment at work place. By implementing the health promotions, events can be averted at the work place are: income losses for employees, wage losses during sickness absence, and wage losses upon return to work. Various programs for lifestyle changes are helpful in reductions in medical treatment costs.

Business

Financial Factors

Occupational health programs implementations can improve productivity, because healthy employees have reduced sick leave (absenteeism) and increased productivity at work (presenteeism). Productivity impact is usually estimated through the calculation of lost working time from absenteeism and presenteeism, and converted into monetary

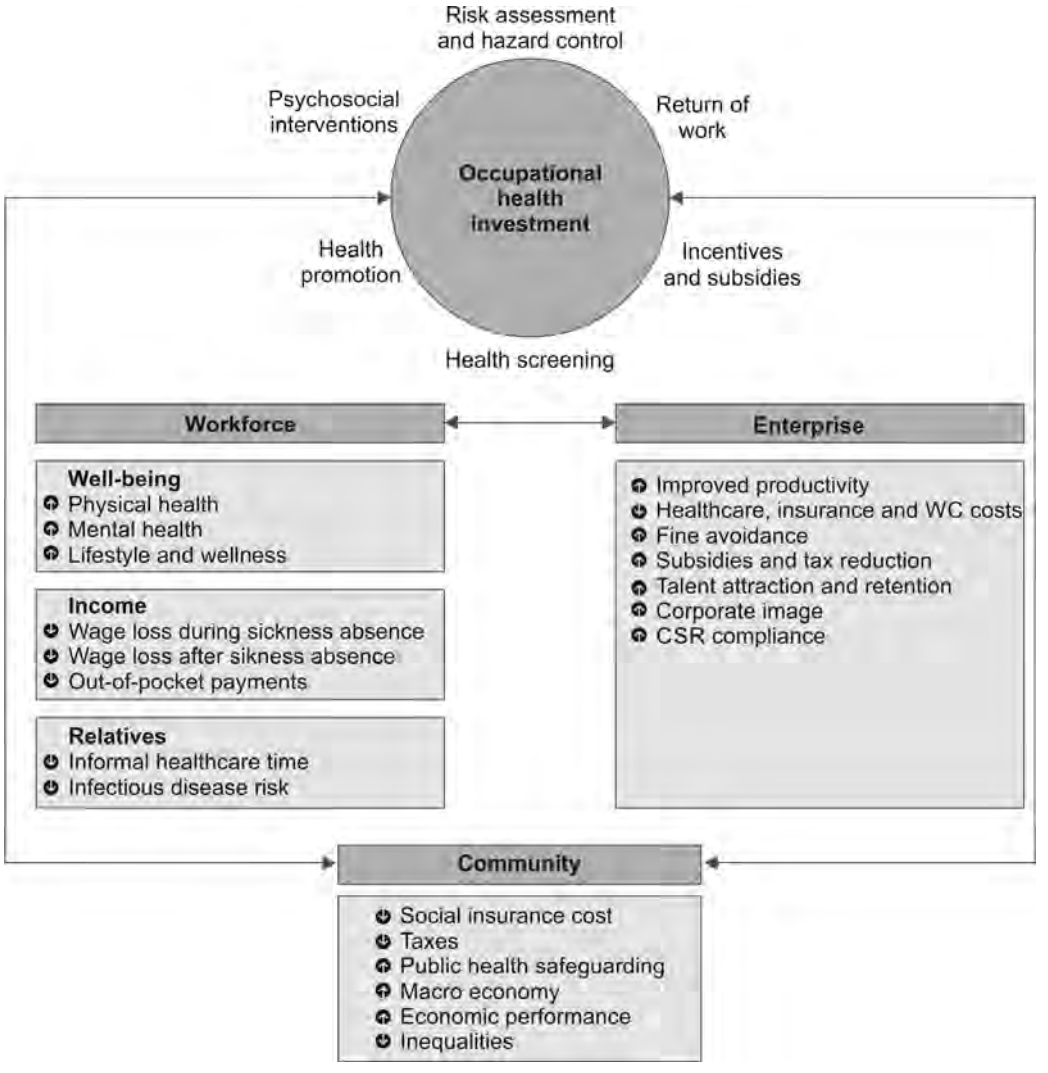

FIG. 1: Value of occupational health investments by category and interconnection between categories.

values by multiplying with the (average) employee wage. In many setting, OH programs are of crucial importance and cost-effective and shown to be helpful in the prevention of absenteeism.

Nonfinancial Factors

Full benefit of OH programs cannot be estimated by financial factors alone. Quality or efficiency is more important than to financial parameters. Companies investing in OH can attract more and more talented workers and lower recruitment and human resource (HR) management costs, finally affect the productivity of the firm.

Society

Public Health

Occupational health interventions can play an important role in safeguarding public health, particularly in outbreaks of infectious diseases or health-related disasters. Exposures increase the risk of acquiring communicable diseases, such as hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) in the healthcare worker. Vaccination reduces the risk of influenza hepatitis, tuberculosis, or HIV. OH can therefore play a crucial role in emergency response. The World Health Organization recommendations during outbreak of coronavirus disease 2019 (COVID-19) are to prevent infections at work, not only for healthcare, transport, or burial team members but also for employers and employees in general. Further protecting or vaccinating employees to avoid a communicable disease can prevent infection for many other parties, such as the employee's family, nonprotected coworkers, and customers. OH not only plays an important part in communicable diseases but can also be of significant in other disasters.

Economic Performance

At the national level, a link between economic performance and OH can be taken as good indicator. All stakeholders get benefits from investing in OH. Employees get improvement in well-being and health. Companies get increased productivity (through reduced absenteeism and presenteeism); decreased compensation and healthcare expenses; and improved reputation.

WORK ENVIRONMENT

Work place is assessed related to occupation, work, and work environment. Workplace should be inspected for actual

TABLE 1: Potential health hazards.	
Air contaminants	• *Particulate contaminants*: Dust, fume, mist, and aerosol fibers • *Gas and vapors contaminants*: Gases vapors
Chemical hazards	Harmful chemicals in the form of solid liquid and gas, mist, dust, fumes exerts toxic effects by inhalation, absorption, and ingestions
Biological hazards	Exposure to bacteria virus fungi and other living organism while working in laboratory can cause acute and chronic infections
Physical hazards	*Noise radiations*: Ionizing and nonionizing radiation and radiant heat exposure
Ergonomic hazards	Excessive vibration, noise, eye strain, repetitive motion, heavy lifting problem, poorly designed tools, and work area
Psychological factors	Stress, production pressure, low pay, and lack of recognition
Technique used in recognizing health hazards	
Material inventory	Check who is using inventory (purchasing staff, safety adviser, occupational hygienist doctors' nurses). Obtain information about nature of material, use of material, their storage handling and control procedure, administrative details, trade and chemical details, use, and waste disposal
Process inventory	Assess and document hazards associated with every process. Process inventory should include process, material involved, point of material entry and exit, operating procedure, and potential exposure
Walkthrough occupational hygiene survey	Preliminary assessment of premises plant operation should be done by walkthrough survey to identify potential hazards. Walkthrough survey is helpful in interacting with plant personnel, engineers, and foreman who know the problem in process and also able to tell complaints and symptoms among workers
Air sampling program	Essential for health risk evaluation, environmental protection, compliance, process control, source identification, and documentation of exposure
Controlling hazard	
Engineering control	Reducing or removal of hazard at source, elimination of toxic chemical, and installing general and local ventilation
Work practice control	Change in existing work process, maintain process and equipment in regular basis, good housekeeping, and prohibiting smoking and chewing tobacco in regulated areas
Administrative control	Limit hazard exposure by scheduling task and production, use of appropriate personal protective agents

hazard and unsafe worker behavior. Assessment of workplace environment is required to monitor stresses arising from workplace environment which may cause injury and sickness, impaired health and significant inefficiency among worker and also community. Assessment of workplace environment include study of toxicology, industrial process, environmental sampling, chemical and physical components of air, evaluation of ventilation system, noise control, protection from radiation, occupational hazard, and effect on health. Worksite analysis is the essential procedure to determine what job or workstation is the potential source of health-related problem (**Table 1**).

OCCUPATIONAL AND OTHER WORK-RELATED DISEASE

Understating between work and health is essential. Interaction between man, environment, and work give rise to various types of stress and hazard that may be present in different type of occupation including industries, agriculture, etc. Occupational diseases are spectrum of work-related disease where causative factors related to health at the work place fully identified, measured, and controlled. Work-related disease may have weak inconsistent relationship to working conditions and their strength and magnitude may vary. Occupational disease can be defined as adverse health conditions of the human beings, severity of which depends on exposure of the factors on the workplace. Factors may be as follows:

- *Physical*: Heat, noise, and radiation
- *Chemical*: Solvent, pesticide, heavy metal, and dust
- *Biological*: Tuberculosis, hepatitis B virus, and HIV
- *Ergonomics*: Poorly designed tools at work area and repetitive motion
- *Psychological stressors*: Excess workload and inadequate personal support
- *Mechanical*: Responsible for injuries and accident rather than occupational disease.

Occupational diseases may be overlooked by physician due to its specific characteristics. Most occupational diseases have similar clinical and pathologic features as nonoccupational disease (asthma due to toluene diisocyanate may not be clinically differentiated from asthma due to other cause). Occupational disease may occur after termination of exposure (asbestos-related mesothelioma occurs 30–40 years after the exposure). Clinical manifestations of occupational disease are dose and exposure time-dependent and occupational and nonoccupational factors both act in combination to produce the disease. Work-related disease are multifactorial and often more common than occupational disease, therefore they need special attention by health service infrastructure which incorporates the OH services. Work-related diseases which need special attention are behavioral

and psychosomatic disorder, hypertension, coronary artery disease, peptic ulcer, nonspecific respiratory disease, and locomotor disorders.

EARLY DETECTION OF OCCUPATIONAL DISEASE

Early detection of pathological changes is necessary to minimize the damage caused by occupational disease. Certain occupational disease presents as early clinical, functional, biochemical, physiological, and morphological changes and are reversible if detected and managed early. Periodic examination is important in early detection of occupational disease. Periodic examination should include simple screening test, positive cases should then undergo comprehensive examination to confirm or exclude the diagnosis of occupational disease. Early detection of occupational disease caused by biological agents: Pulmonary tuberculosis can be detected by X-ray; hepatitis B and C, HIV, and brucellosis can be detected by serologic examination. Early detection of occupational disease caused by physical factors is summarized in **Table 2**. Early detection of occupational disease caused by heavy metals is summarized in **Table 3**. Early detection of exposure of organic solvent is summarized in **Table 4**.

OCCUPATIONAL ERGONOMICS

Ergonomics is the understanding of complex relationship between human-machine and environment. Ergonomics also includes study of physical and psychological aspect of work environment (facility, equipment, and tools) in relation with the workers. The fundamental principle of ergonomics is that all type of work activities gives some kind of physical or mental stress to workers. To keep work performance satisfactory, this stress level should be kept within reasonable limit and worker's health and well-being should be monitored. The aim of ergonomics is to optimize comfort, health, safety, and efficiency of the workers. Benefits to employers can be measured in terms of increased efficiency and productivity reduction in work time loss in illness or injury and decreased insurance cost. Ergonomics has four major components: (*1) Human factor engineering, (2) Work physiology, (3) Occupational biomechanics, and (4) Anthropometry.*

Human factor engineering also called engineering psychology related to information processing aspect of the work and objective are to design procedures, equipment, and work environment to minimize the likelihood of accidents caused by human error. *Work physiology* is subdiscipline of ergonomics which concern with stress due to metabolic conversion of biomechanical energy source, glucose to mechanical work. Workers will feel fatigue if stress is excessive. Jobs which require highly repetitive and forceful exertion, injury may occur to musculoskeletal tissues and peripheral nerves. *Biomechanics* is subdivision of ergonomics related to mechanical properties of the human tissue, concern with resistance of the human tissue to the stress. Occupational biomechanics especially focus on prevention of stress of lower back and upper extremities. *Anthropometry* is concern with matching tools and workspace to the dimensions of the human body (workers). Mismatch in size between worker and workplace equipment or machinery increases the physical

TABLE 2: Early detection of occupational disease caused by physical factors.

Heat	Irritability, discomfort, lassitude, lack of concentration, low work performance, heat rash, heat exhaustion, and heat stroke
Noise	Noise-induced hearing loss can be detected by audiometry
Vibration	Vibration causes vascular disorders of arms and changes in small bones of the wrist. Vascular changes difficult to detect early but X-ray can be helpful in detecting rarefaction of lunate bone
Atmospheric pressure	Aseptic bone necrosis around knee, hip, and shoulder after exposure to increased atmospheric pressure can be detected by X-ray
Infrared radiation	Cataract can cause progressive failure of vision and can be detected by slit-lamp examination
Ionizing radiation	Ionizing radiation exposure can also cause cataract. Bone marrow can be affected so periodic complete hemogram can be done and leukocytes must be evaluated

TABLE 3: Early detection of occupational disease caused by heavy metals.

Lead	• *Acute effects*: Abdominal pain, encephalopathy, hemolysis, and acute renal failure • *Chronic effects*: fatigue, arthralgia, myalgia, anemia, gout, and neuropathy • *Lead concentration in blood can be determined*: Lead poisoning >80 µg/dL
Mercury	*Acute respiratory distress, gingivitis, tremor, proteinuria, renal failure, ataxia, spasticity, paresthesia, and visual and auditory disturbance*: Early detection of exposure to mercury is carried out by estimation of mercury in urine (<20 µg/L in nonexposed individuals)
Manganese	*Fever, chills, dyspnea (metal fume fever), pneumonia, Parkinson-like syndrome, and behavioral syndrome*: Diagnosing the disease on the basis of neuropsychiatric clinical staging is helpful not the estimation of manganese in body fluids
Arsenic	• *Acute*: Nausea, vomiting, diarrhea, intravascular hemolysis, jaundice, and oliguria • *Chronic*: Hyperkeratosis, hyperpigmentation, and cardiac and peripheral vascular disease • Chronic exposure of arsenic can be estimated by measurement of arsenic in urine (in nonexposed normal individuals <30 µg/L). Estimation of arsenic in hair or in nails also good index of chronic arsenic exposure

stress in workers. This mismatch makes the worker to adjust, need to bend over for work, having to work with one or both arm and should held high for longer period of time, and having to sit over bench which is too high or too low.

STRESS AND ADVERSE PSYCHOLOGICAL FACTORS AT WORK

Stress is the imbalance between demand and response capabilities and failure to achieve demand is important consequences. Health, health services, and community are influenced by psychological factors. Common workplace stressors and their prevention and control are summarized in **Table 5**.

OCCUPATIONAL SAFETY AND ACCIDENT PREVENTION

Occupational accidents occur at the workplace, which may cause damage to machinery, tools, and people (bodily injury or death). Occupational safety measure to be implemented with the aim to avoid any destruction of health and other

TABLE 4: Early detection of exposure of organic solvent.

Organic solvent	*Clinical features*	*Method of evaluation of exposure*
Benzene	• *Acute*: Anesthesia, nausea, vomiting, headache, sleepiness, fatigue, slurred speech, disequilibrium, and depression • *Chronic*: Bone marrow, depression, and aplastic anemia	• Periodic hemogram may detect early hemopoietic abnormalities • Benzene in blood • Benzene, trans trans-muconic acid, and phenylmercapturic acid in urine
Methylbenzene (toluene)	• Isolated toluene exposure is rare usually with benzene • Conjunctival irritation and ulceration cardiac arrhythmia • Liver and kidney dysfunction and bone marrow depression in chronic exposure	Hippuric acid in urine collected at the end of work shift (hippuric acid is not a metabolite of toluene)
Xylene	• Mucus membrane irritation • Chronic exposure may cause aplastic anemia	Methylhippuric acid in urine
Aminobenzene (aniline)	Mild skin irritant, cyanosis in moderate exposure, anoxia and death in severe exposure	• Methemoglobin in blood • Para-aminophenol in urine
Carbon tetrachloride	Nausea, vomiting, drowsiness, dizziness, and chronic exposure causes scaly dermatitis and liver and renal dysfunction	Carbon tetrachloride in exhaled air, blood concentration level has limited value
Polychlorinated biphenyls	• Skin rash, eye irritation, nausea, and vomiting • Chronic symptoms include anorexia, weight loss, and liver dysfunction	Hemogram
Methylene chloride (dichloromethane)	*Skin and mucous membrane irritant*: Acute intoxication after inhalation (stupor, tingling, and numbness of limbs), dry scaly dermatitis, and cardiac dysfunction due to carboxyhemoglobin	Carboxyhemoglobin level in blood and carbon monoxide level in exhale air

TABLE 5: Common workplace stressors and their prevention and control.

Common workplace stressors	• *Organizational*: Change, inadequate communication, interpersonal conflict, and conflict with organizational goals • *Career development*: Lack of promotional opportunities and new responsibilities beyond capabilities • *Role*: Role conflict, role ambiguity, inadequate resource, and authority to accomplish the job • *Task*: Quantitative and qualitative overload • *Work overload*: Poor aesthetics, physical exposure, ergonomics problem, noise, odor, and safety hazards
Prevention and control of stress	• *Treat individual*: Medical treatment of hypertension, backache, and depression • *Employee assisting program*: Smoking, alcohol, and drugs • *Reduce individual vulnerabilities*: Individual or group counseling • *Training program*: Relaxation, medication, and biofeedback • *General support*: Exercise program and recreational activities • *Organizational*: Attitude survey, development of flexible and responsive management, improve internal communication, supervisor training, and management development

TABLE 6: Examples of overt and cumulative trauma affecting occupational group and prevention.

Causes	*Injury/disease*	*Affected occupation*
Overt trauma		
Mechanical energy	Laceration	Sheet metal workers, press operator, and fabric cutters
	Fracture	Material handler's, miner, and construction workers
	Contusion	Workers exposed to low energy impact and material handlers
	Amputation	Press operator and machine operators
	Crush injuries	Material handler's, press operator, and construction workers
	Eye injury	Miners, grinders, and saw mill operator
	Strain/sprain	Material handlers and construction workers
Thermal energy	Burns	Foundry smelter and glass worker welders
	Heat strain	Firefighter smelter and steel workers
	Cold strain	Utility workers
Chemical energy	Burn	Hazardous waste worker and process workers
	Asphyxiation	Firefighter, hazardous waste worker, and confined space workers
Electric energy	Electrocution, shock, and burn	Utility workers, construction workers, and electricians
Nuclear energy	Radiation burn and illness	Hospital workers, industrial radiographers, and nuclear workers
Cumulative trauma		
Heavy lifting and prolonged awkward position	Back pain	Material handlers, nurses, truck drivers, and sewing machine operators
Vibrations	Raynaud's phenomenon	Lumberjacks, grinding machine operator, and jackhammer operators
Control and prevention of occupational accident		
• Contain hazard from machine by enclosing and guarding them • Train operating personnel • Prescribe personal protective agent to worker to safeguard from hazard • Provide advisory services on safety and health problem • Develop centralized program to control accident and hazard • Develop and apply safety standard • Coordination between engineering, industrial hygiene, and medical purchasing department to ensure purchase of safe tools, equipment, and supplies • Collect and analyze data on illness and injuries • Ensure education and training of employee in specific health and safety principles and technique		

resources, prevent insufficiency at workplace due to accident, prevent social harm due to accident, and promote accident prevention to raise the morale of workers. Common types of occupational accidents are falls or struck by material, striking against objects or trap between the objects, strenuous movement, exposure to extreme temperature, electric current, and radiations. Occupational accidents give rise to various types of injuries, wound, fracture, dislocation, burn, poisoning, and diseases. Various parts of the body such as head, neck, thorax, abdomen, and upper or lower extremities can be affected by occupational accident. Few examples of overt and cumulative trauma affecting occupational group and their prevention are summarized in **Table 6**.

EPIDEMIOLOGY AND BIOSTATISTICS IN OCCUPATIONAL HEALTH

Occupational health is considered as components of public health. Epidemiology and statistics are the key disciplines of public health and population-based studies are an integral part of OH practice. Epidemiology is the study of the distribution and determinants of the health problem in the population and application of the study to control the health problem. Occupational epidemiology is related to study of occupational disease and their determinants. Important questions during investigations are who is at risk, where is the risk, and when and how? Biostatistics associated with description, summarization, and interpretation of data also in development of procedure. Epidemiologic study measures risk of disease in human population. Three types of epidemiologic study usually carried out: (1) Descriptive, (2) Analytical, and (3) Interventional (rarely done). Cohort study is commonly performed in occupational epidemiology.

RECORD KEEPING

Keeping worker's health record and reporting is important in OH. Coding system should be used while maintaining the health record. Record keeping is important even in small OH services. In an OH records can be used for documenting

exposure to hazards, employee health data for job placement, documenting employee health overtime, and fulfillment of regulatory requirements. There are seven types of basic health record on workers' health: (1) health and safety inspection, (2) environmental monitoring, (3) health monitoring, (4) first aid provided in workplace, (5) accident investigations, (6) sickness certificates, and (7) personal health records. Record keeping should be in simplest, consistent, convenient, efficient, and economical manner but with controlled access. Computer storage permits automatic and rapid retrieval of data in any combination and desired sequence. It is recommended to secure the record for 30 years and in some countries mandated by law as well.

OCCUPATIONAL HEALTH FOR WOMEN

Women workforce increasing day by day all over the world, women work very hard not only as housewives and mother but also in different sectors. Working women are in increased risk for fatigue, malnutrition, stress, and exposed to various types of hazards at the workplace. Industrial expansion in many countries happens without sufficient protective measures for female workers. Also, women are under stress since their work is considered secondary importance by management and medical facilities are also inadequate. Stress-related issues present in nearly all jobs held by women, mostly are low-paying job and even create more stress for single mother and home obligation for children. Women are at more risk of chemical agent, toxic substance such as organic solvent are more likely to retain in women bodies due to high fat content and may causes menstrual disturbance and spontaneous abortion. Women working in agriculture industries exposed to pesticide fertilizers and at risk of infertility and women working with textile mill exposed to dust which causes byssinosis. Women working in textile industries are exposed to noise vibration, heat, and stress which may lead to low birthweight babies. Women working in agriculture sector exposed to snake bite, tetanus, and worm infestation. Nurses are exposed to tuberculosis, hepatitis B and C, rubella, and other biological agents. Women workforce more likely to face ergonomic problem because most of the industrial and agricultural process and machine are designed for male bodily dimension and female workers find difficulty to operate them. To ensure safety and maintain total health in working women OH services should be established at all work places. Points to be implemented in OH care programs for working women are: (1) special health education, (2) regulations to safeguard working women, (3) environmental monitoring, (4) preplacement medical examination, (5) periodic medical examination, (6) equipment design, (7) emphasis on underserved working women, (8) research and survey, (9) and while planning the primary healthcare (PHC) services for working women address issues related to them maternity protection, family planning, and counseling.

SUMMARY

Occupational health has progressed from monodisciplinary, risk-oriented activity to multidisciplinary and comprehensive approach that works towards individual's physical, mental, social well-being, general health, and personal development. OH is multidisciplinary activities help in preventing and controlling the occupational diseases by eliminating occupational factors. OH activities enable workers to conduct socially and economically productive lives to contribute positively to sustainable development.

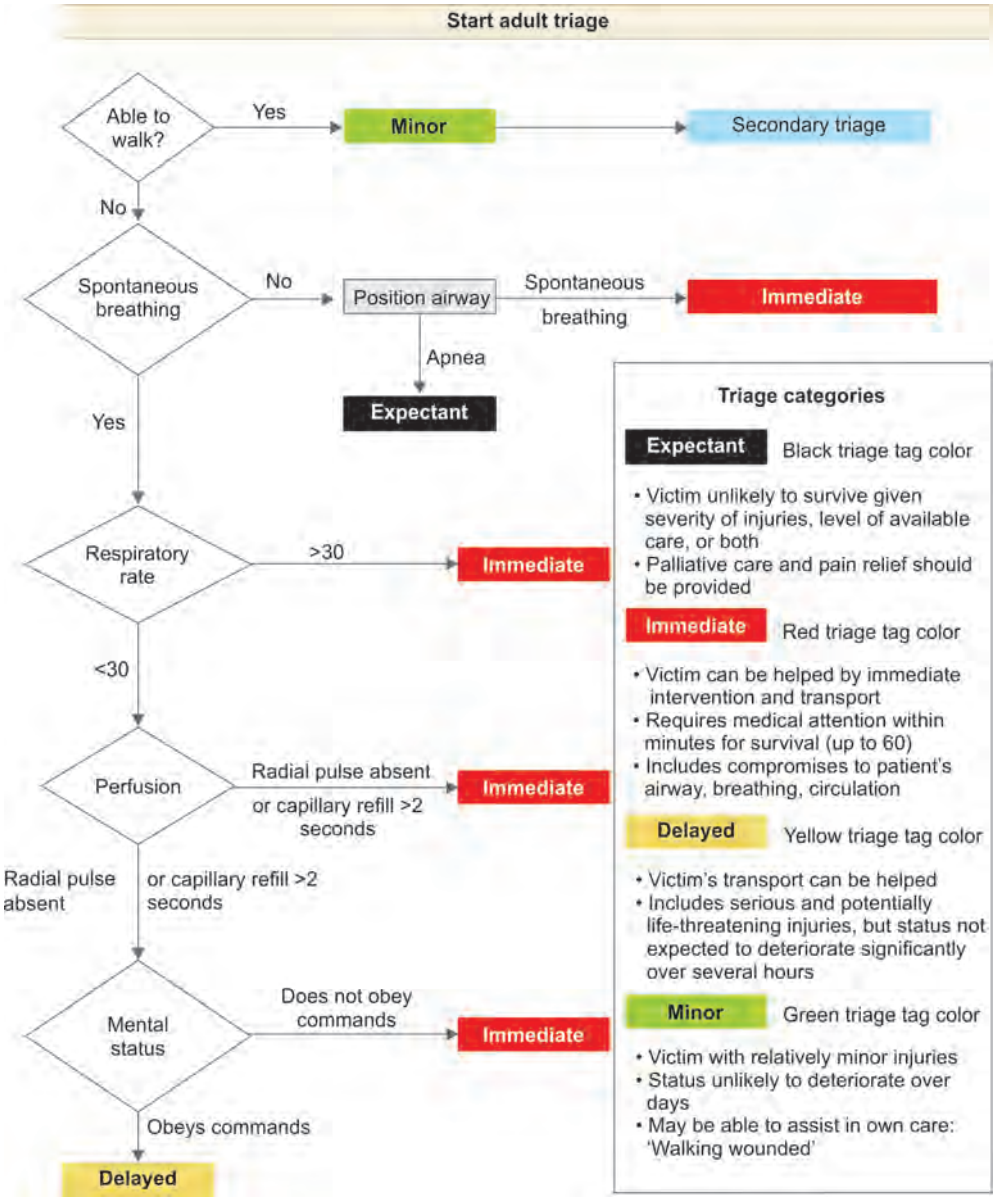
PLATE 1

FIG. 2: Personal protective equipment levels. ***(Chapter 29)***



(START: simple triage and rapid treatment)

FLOWCHART 1: START adult triage algorithm. ***(Chapter 29)***

PLATE 2

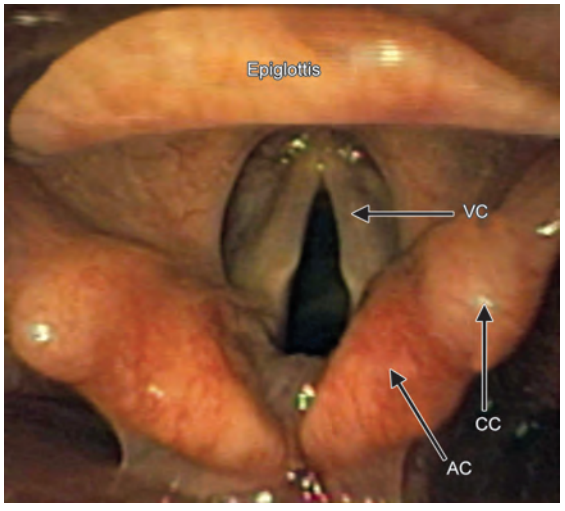


FIG. 7: Laryngoscopic view—anatomy of the laryngeal inlet revealed at direct laryngoscopy. Beneath the epiglottis (E), a view is sought of the whitish vocal cords (VC) in their triangular orientation. The rounded paired posterior (corniculate) cartilages (CC) and arytenoid cartilages (AC) are also shown. ***(Chapter 32)***

FIG. 5: Venturi device. ***(Chapter 36)***

(Chapter 42)

TABLE 3: Selection of peripheral cannula as per prescribed therapy.

Color	*Gauge size*	*External diameter (mm)*	*Length (mm)*	*Water flow rate (mL/min)*	*Recommended uses*
Orange	14G	2.1 mm	45 mm	~240 mL/min	Trauma, Rapid blood transfusion, Surgery[1]
 Gray	16G	1.8 mm	45 mm	~180 mL/min	Rapid fluid replacement, Trauma, Rapid blood transfusion[1]
Green	18G	1.3 mm	32 mm	~90 mL/min	Rapid fluid replacement, Trauma, Rapid blood transfusion[1]
 Pink	20G	1.1 mm	32 mm	~60 mL/min	Most infusions, Rapid fluid replacement, Trauma, Routine blood transfusion[1]
 Blue	22G	0.9 mm	25 mm	~36 mL/min	Most infusions neonate, pediatric, older adults, Routine blood transfusion[1]
 Yellow	24G	0.7 mm	19 mm	~20 mL/min	Most infusions neonate, pediatric, older adults, Routine blood transfusion, Neonate or Pediatric blood transfusion[1]
Purple	26G	0.6 mm	19 mm	~13 mL/min	Pediatrics, Neonate[1]

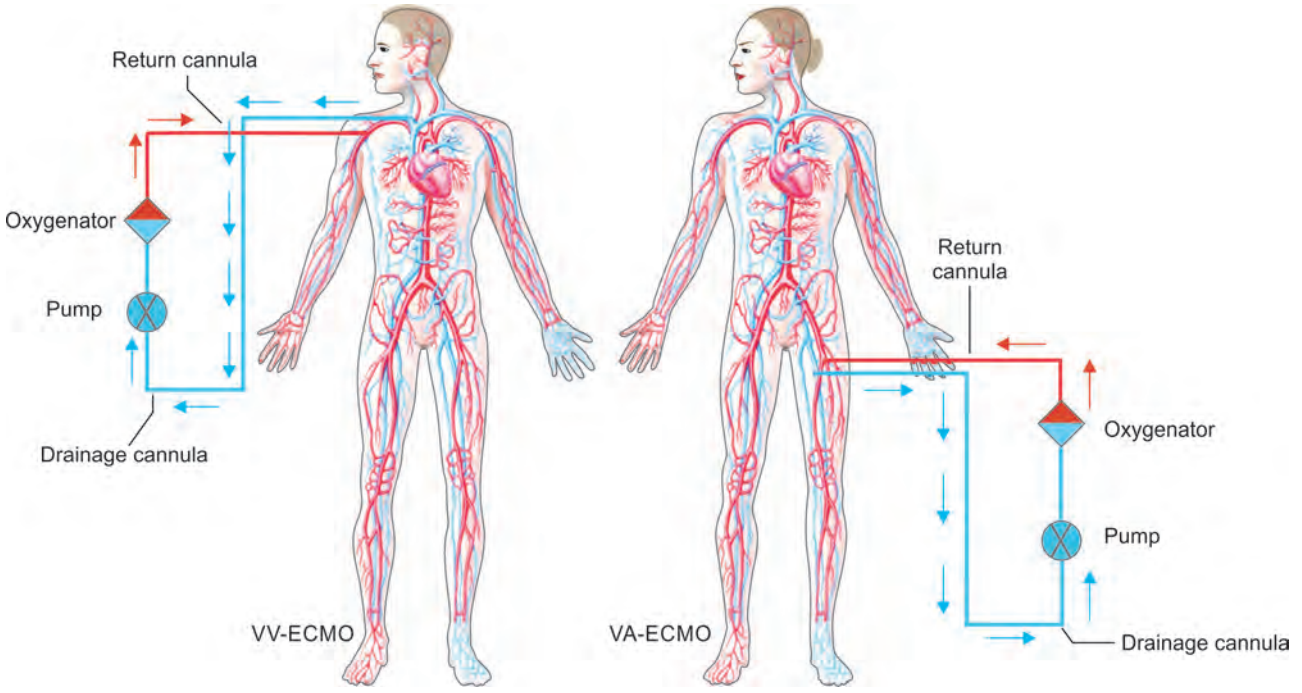
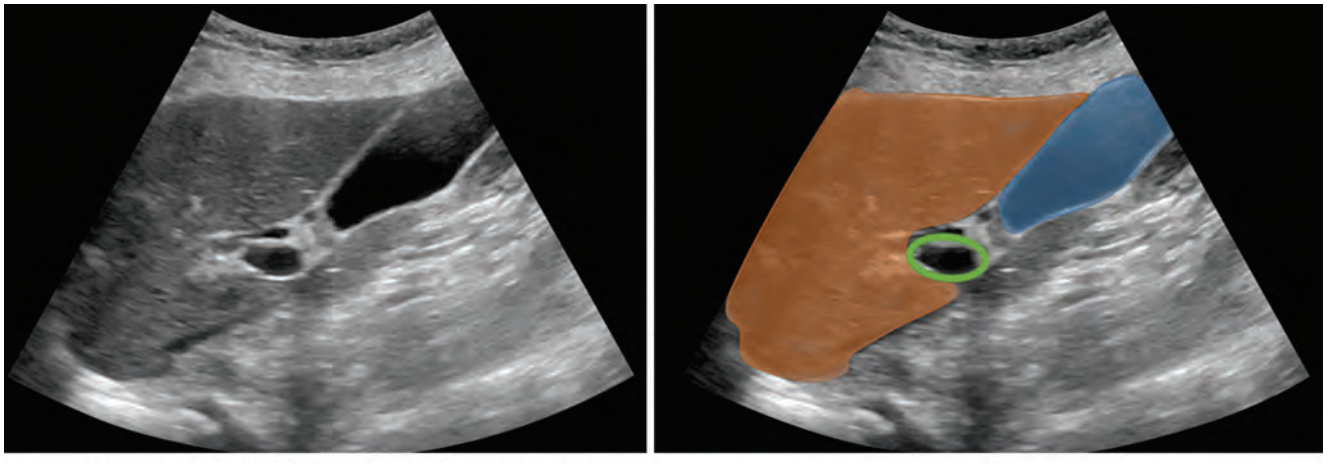
PLATE 3



(VA-ECMO: venoarterial extracorporeal membrane oxygenation; VV-ECMO: venovenous extracorporeal membrane oxygenation)

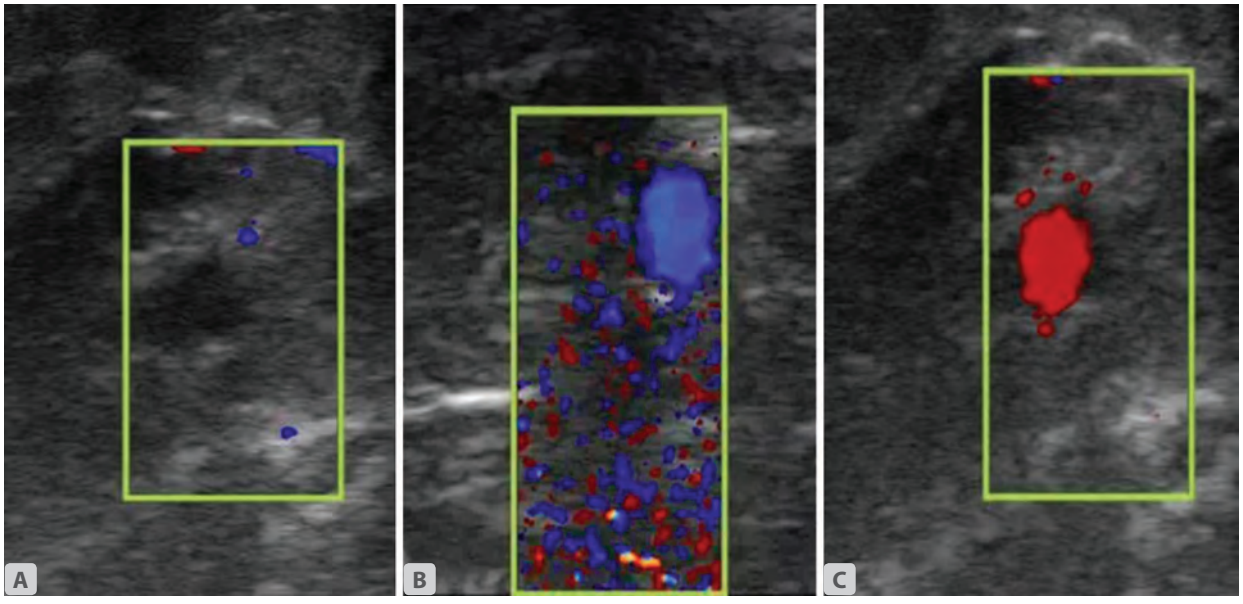
FIG. 1: Typical schematic illustration of VV-ECMO and VA-ECMO supports. ***(Chapter 51)***



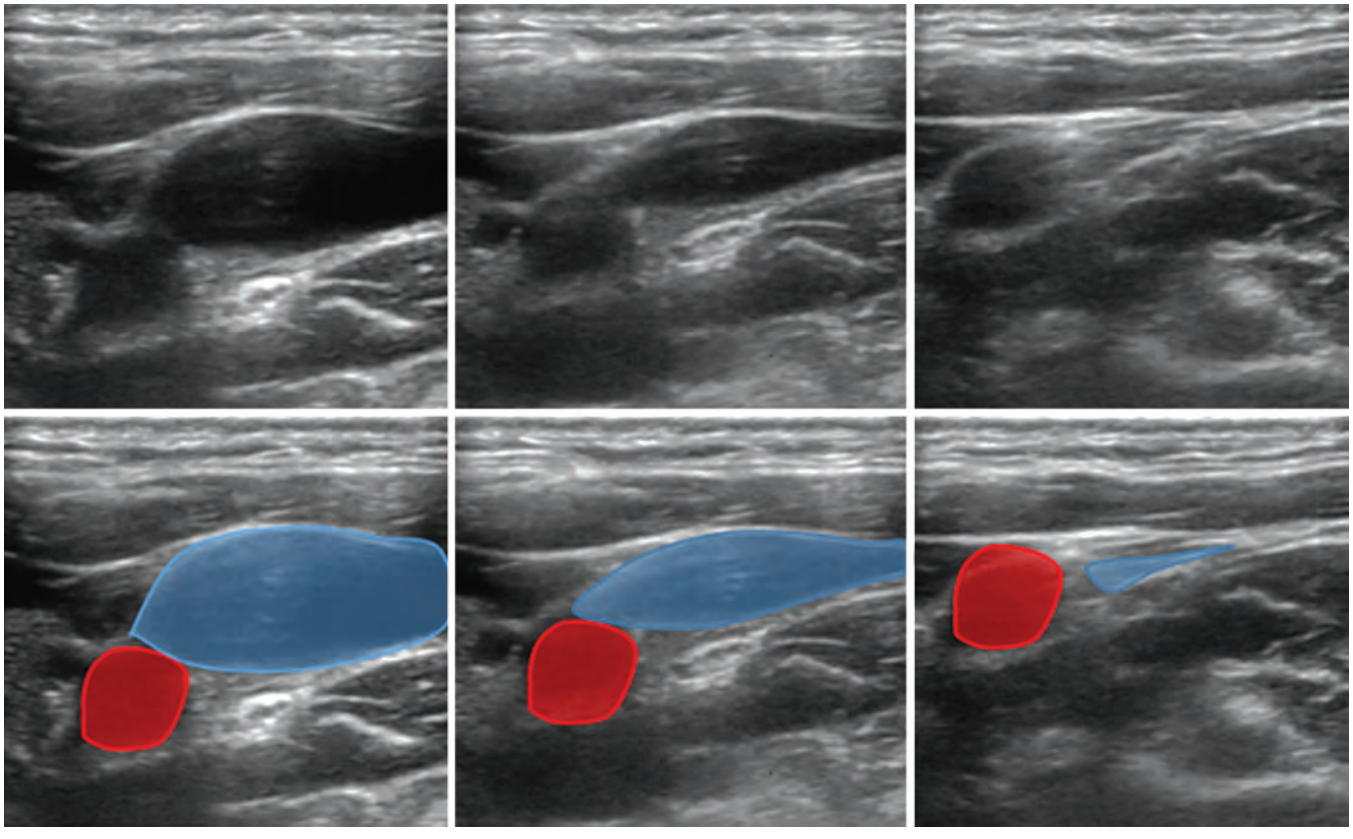
Blue: The gallbladder in longitudinal view is an anechoic structure.
Green: The walls of the portal vein represent a hyperechoic structure.
Orange: The liver parenchyma represents a hypoechoic structure.

FIG. 1: Varying echogenicity of structures seen on ultrasound. ***(Chapter 55)***

PLATE 4



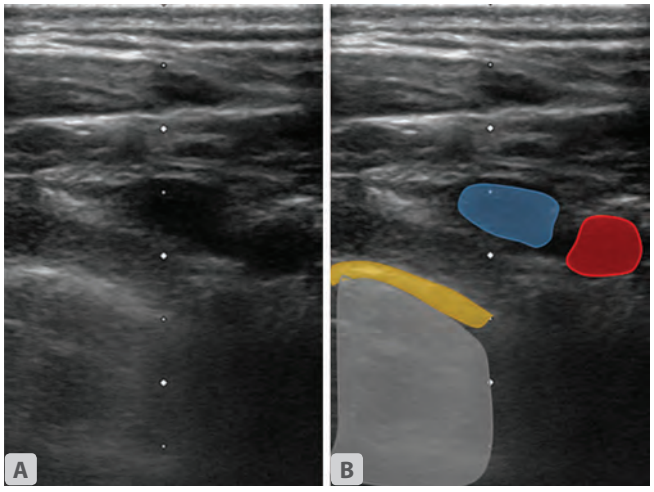
FIGS. 3A TO C: Use of color Doppler to identify vascular flow; (A) A nonvascular structure with no flow seen on Doppler; (B) A vascular structure with flow away from the probe consistent with a vein; (C) A vascular structure with pulsatile flow toward the probe consistent with an artery. ***(Chapter 55)***



(Blue: internal jugular vein; Red: carotid artery. Internal jugular and carotid artery shown from left to right with progressive compressibility of the internal jugular vein)

FIG. 7: Sonographic anatomy of internal jugular vein and carotid artery. ***(Chapter 55)***

PLATE 5



FIGS. 9A AND B: Transverse infraclavicular ultrasound view of the subclavian vessels and lung. ***(Chapter 55)***

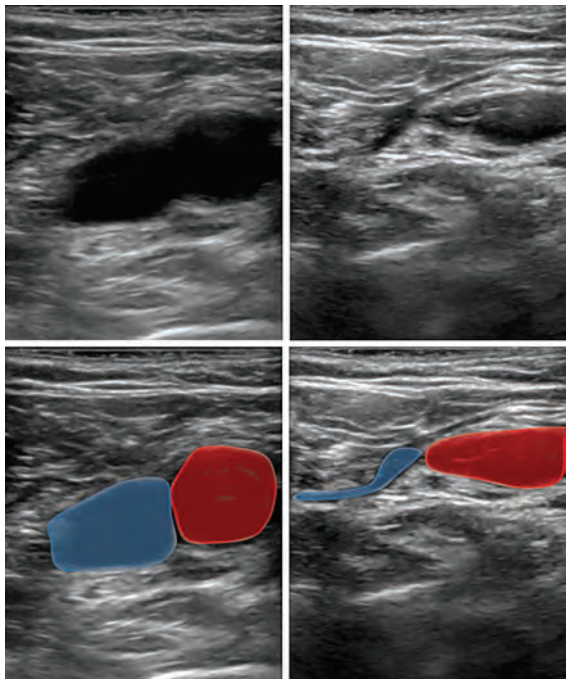


FIG. 11: Ultrasound view of a femoral vasculature with a patent femoral vein. ***(Chapter 55)***

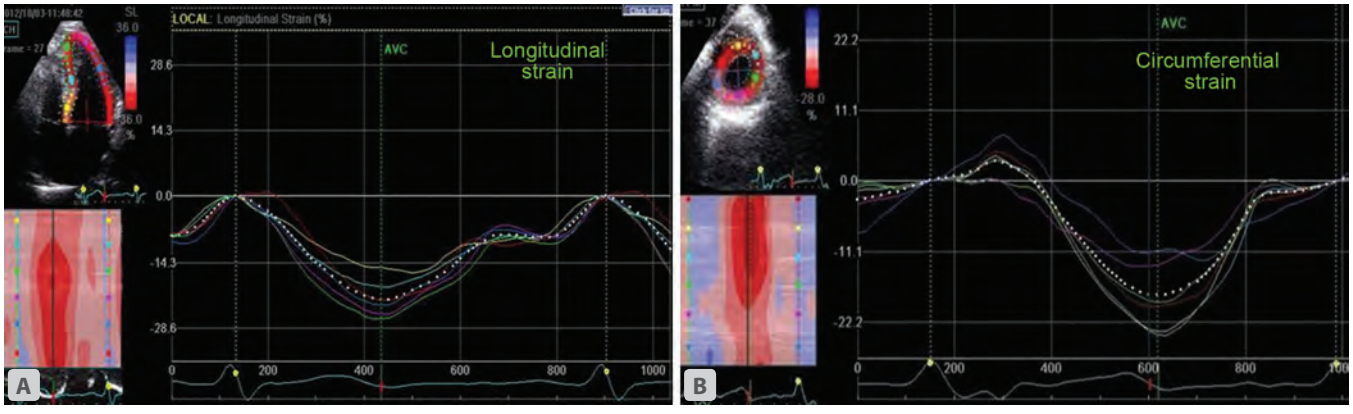

FIGS. 2A AND B: Speckle tracking echocardiography-based measurement of left ventricular longitudinal and circumferential strain. ***(Chapter 63)***

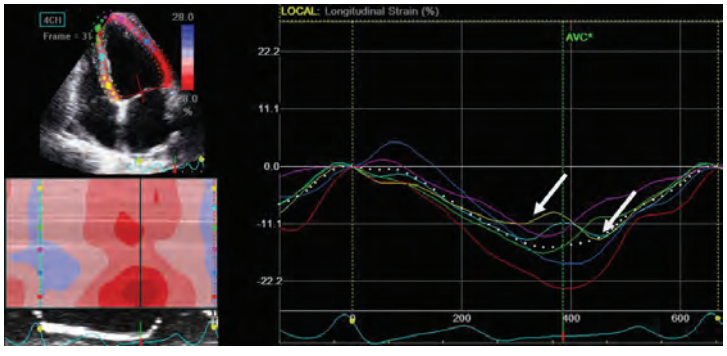

FIG. 4: Reduced systolic longitudinal strain with post-systolic shortening (arrows) in basal septum (yellow trace). ***(Chapter 63)***

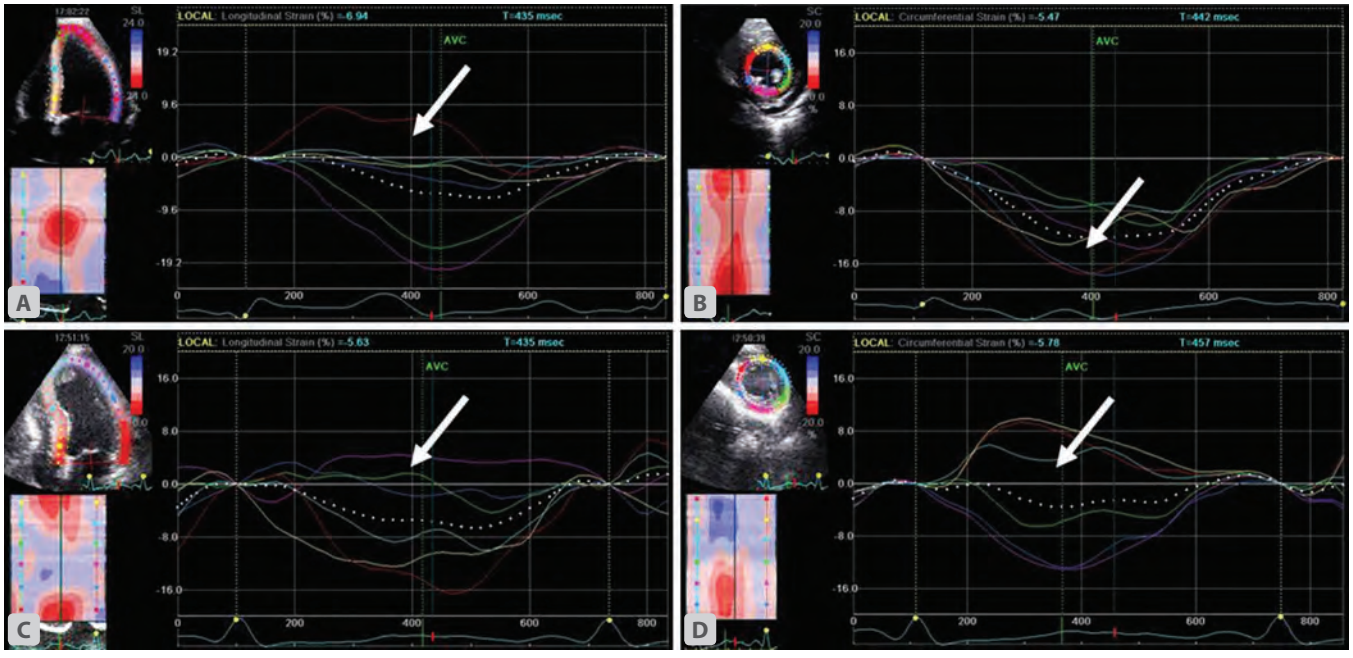
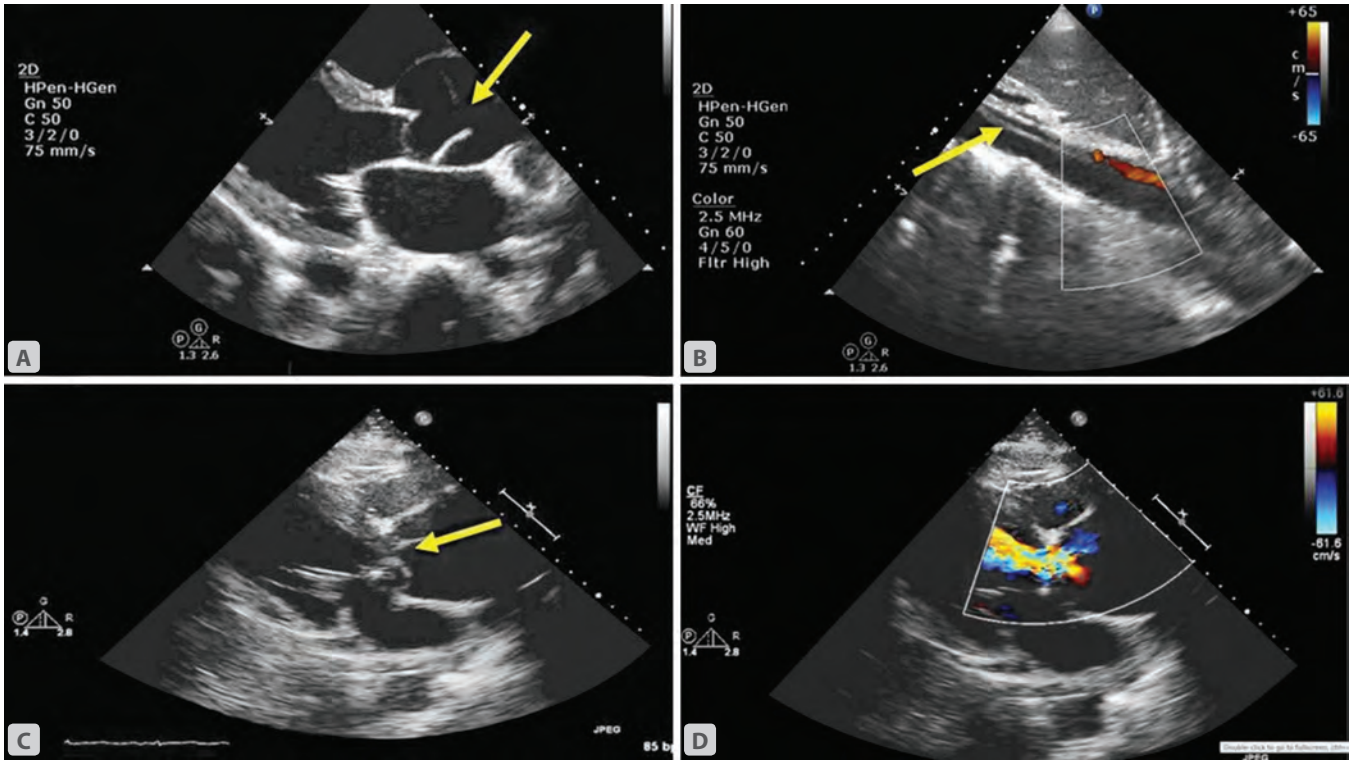
PLATE 6

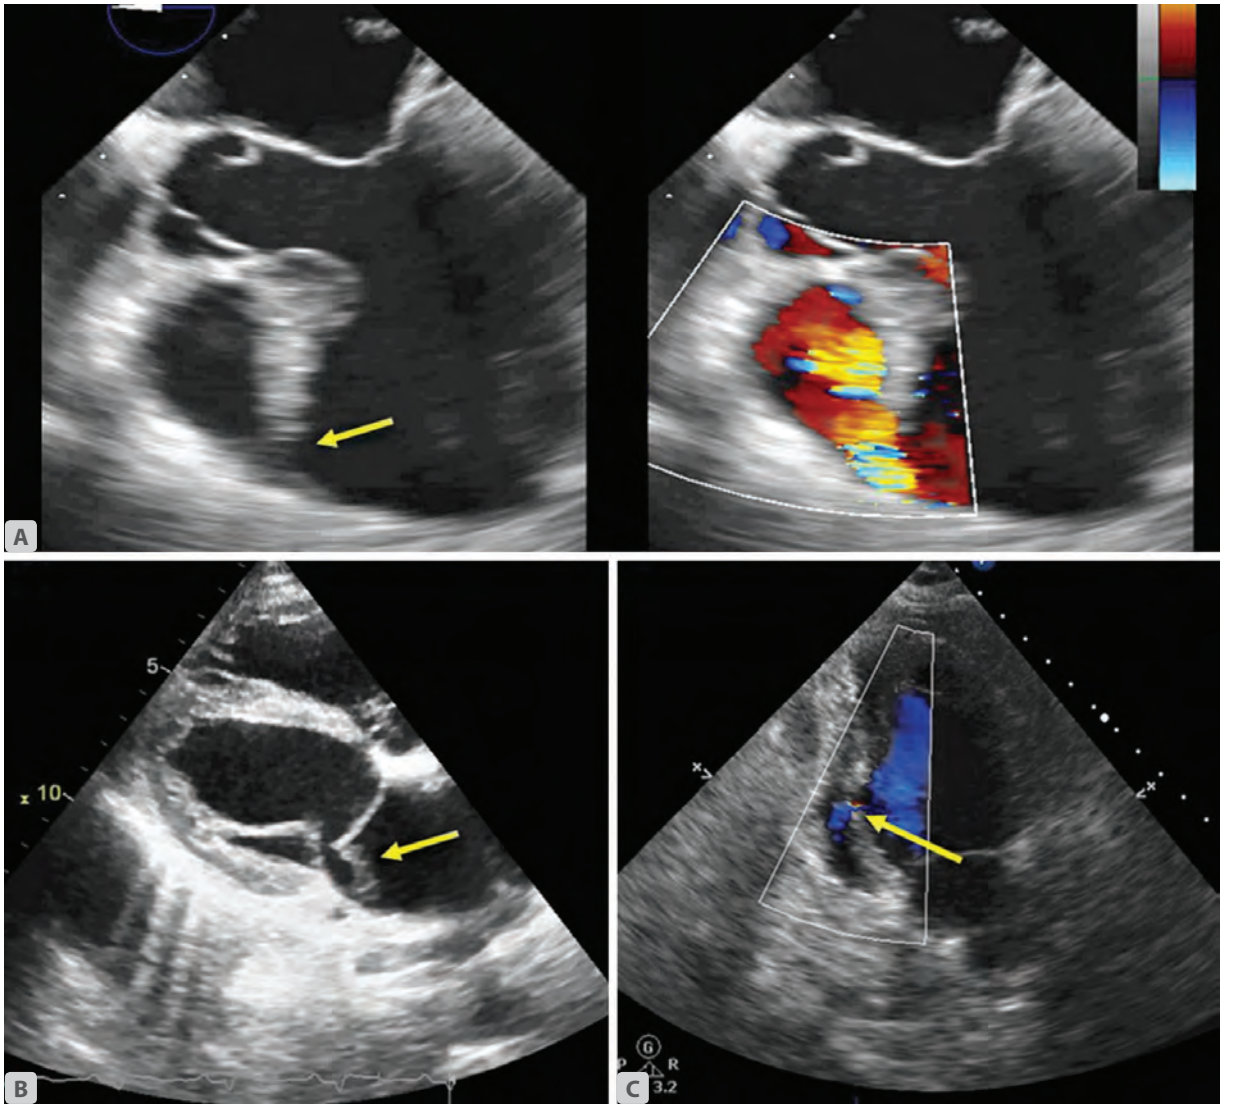


FIGS. 5A TO D: Differential involvement of left ventricular longitudinal and circumferential strain in patients with subendocardial and transmural infarcts. (A and B) Longitudinal strain is impaired (A) but circumferential strain is preserved (B) in basal segments in a patient with subendocardial infarct; (C and D) Both longitudinal and circumferential strains are impaired in apical segments in a patient with transmural infarct. ***(Chapter 63)***



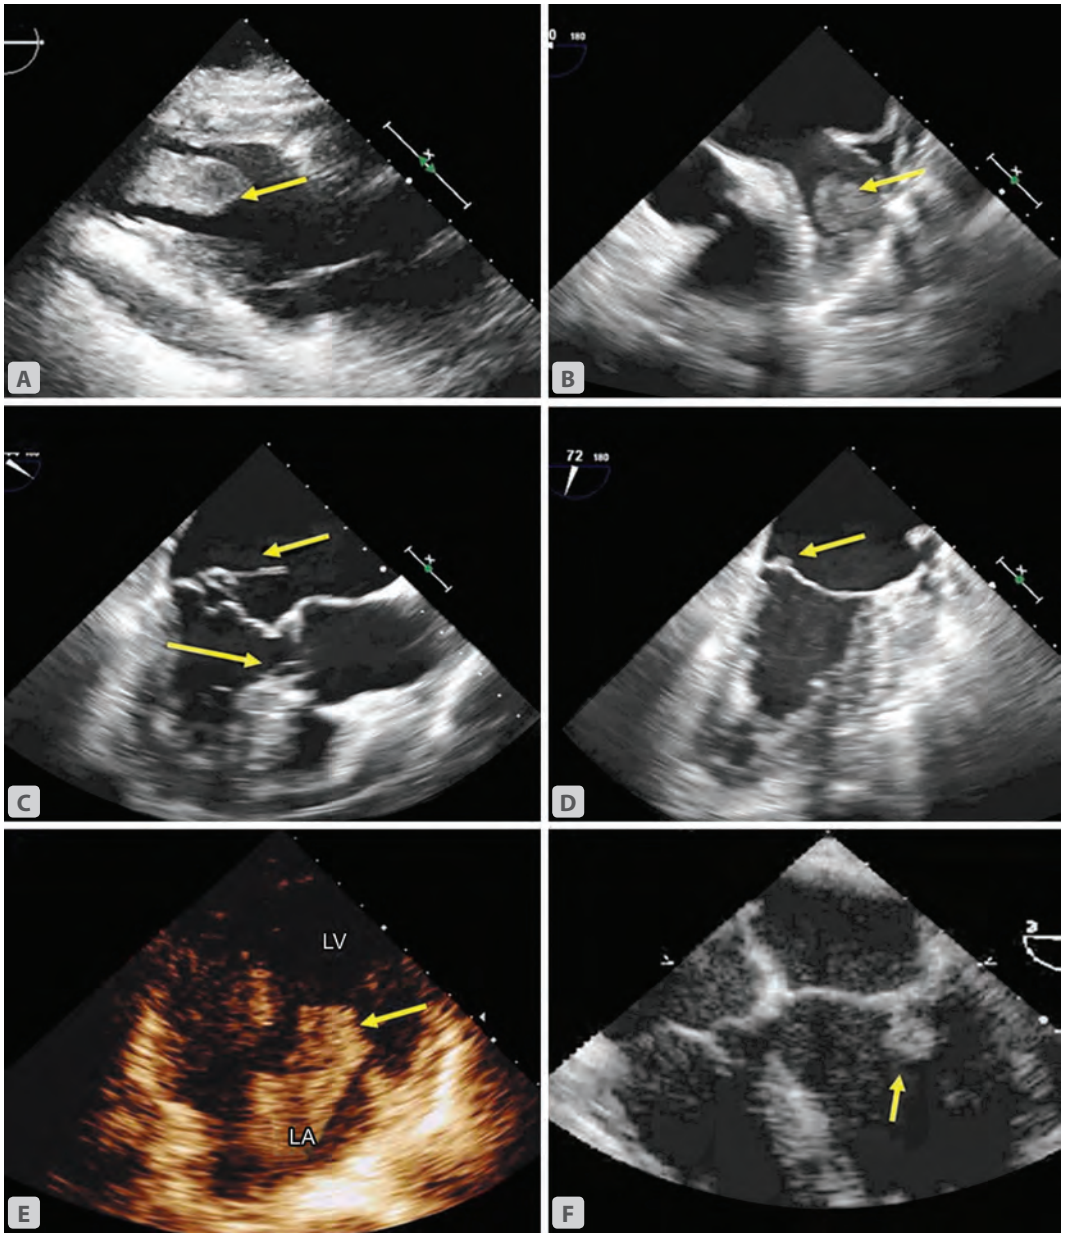
FIGS. 6A TO D: Two examples of acute aortic dissection. (A) Intimal flap (arrow) is seen in the aortic root; (B) In the same patient, the dissection flap (arrow) is seen extending into the abdominal aorta also; (C and D) Intimal flap (C, arrow) in another patient is prolapsing through the aortic valve causing severe aortic regurgitation. ***(Chapter 63)***

PLATE 7



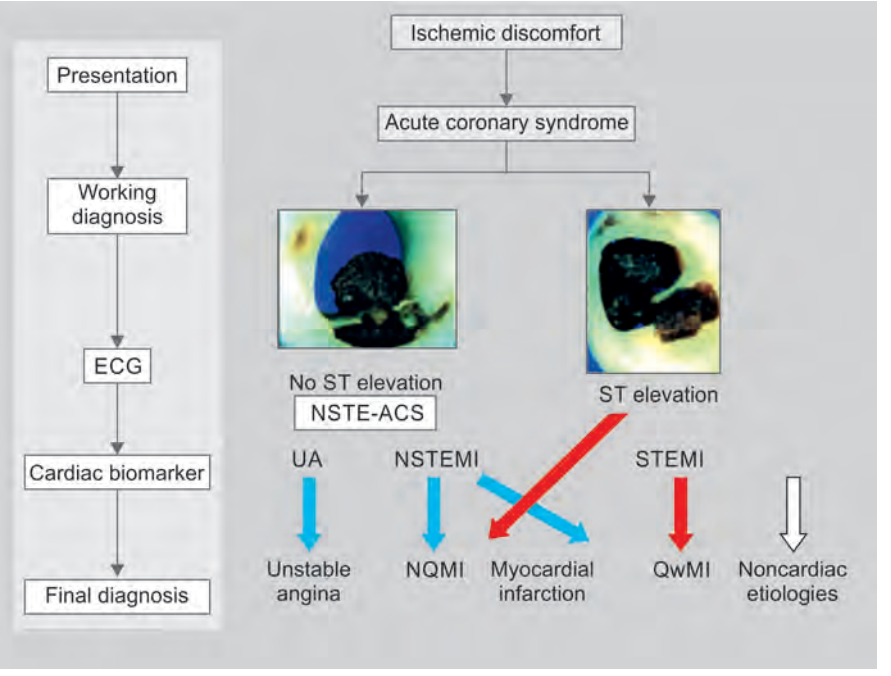
FIGS. 9A TO C: *Examples of mechanical complications of myocardial infarction.* (A) There is apical ventricular septal rupture (arrow) with left to right shunt through the defect; (B) One of the *papillary muscles has got ruptured* and is seen attached to the anterior mitral leaflet and prolapsing into the left atrium. The anterior mitral leaflet itself is flail; (C) Contained *rupture of the inferior wall*. Blood flows through the defect (arrow) into a small pseudoaneurysm. ***(Chapter 63)***

PLATE 8



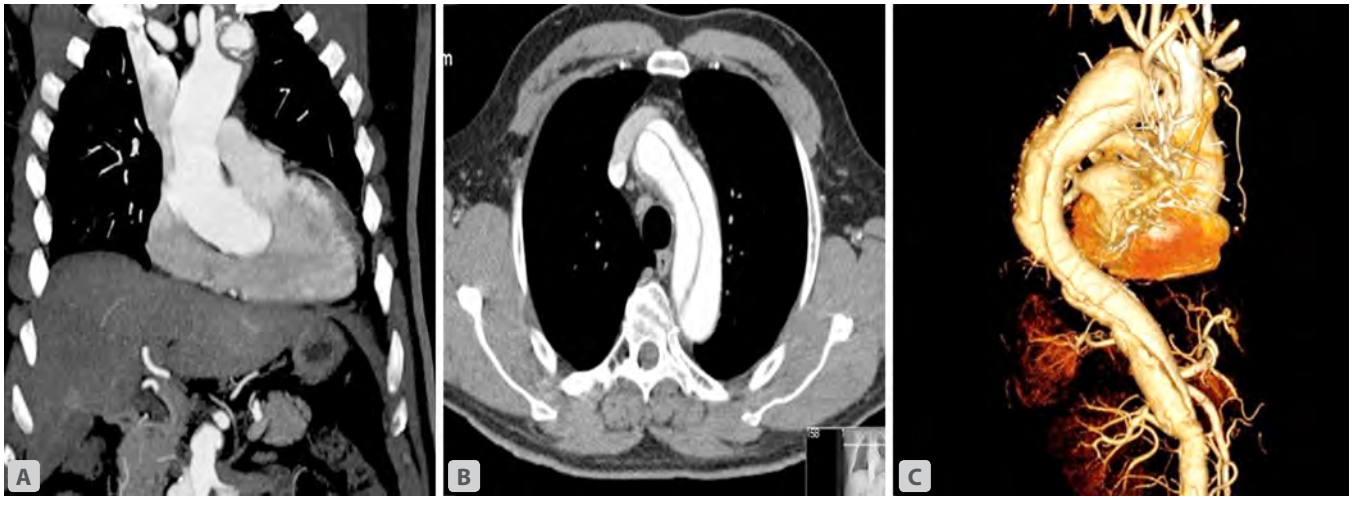
FIGS. 10A TO F: *Common causes of cardioembolic stroke.* (A) Large left ventricular apical clot (arrow) in a patient with anterior wall myocardial infarction; (B) Left atrial appendage clot (arrow); (C) Vegetations (arrows) attached to both mitral and aortic valve leaflets; (D) Sessile vegetation (arrow) on the atrial surface of the mitral leaflet in a patient with non-bacterial thrombotic endocarditis; (E) Large left atrial myxoma (arrow) prolapsing into the left ventricular cavity through the mitral orifice; and (F) Papillary fibroelastoma (arrow) attached to the mitral leaflet. ***(Chapter 63)***

PLATE 9



(ACS: acute coronary syndrome; NSTE-ACS: non-ST elevation ACS: NSTEMI: non-ST-segment elevation myocardial infarction; STEMI: ST-segment elevation myocardial infarction; UA: unstable angina)

FIG. 2: Initial evaluation of an individual presenting with symptoms suggestive of acute coronary syndrome (ACS): ascertaining the type of ACS. ***(Chapter 65)***



FIGS. 5A TO C: (A) Aortic root dilatation; (B) CT angiographic image showing dissection flap in the arch of aorta; (C) CT angiogram in aortic dissection. ***(Chapter 77)***

PLATE 10

FIG. 1: Double-lumen endobronchial tube—blue colored part is the bronchial tube and transparent one is the tracheal tube. ***(Chapter 82)***

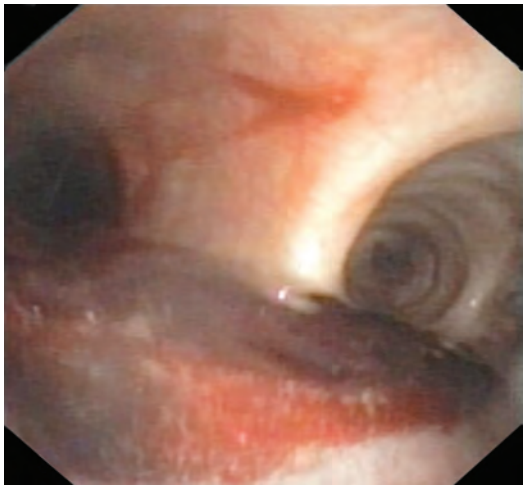


FIG. 5: Bronchoscopy showing bleeding from left main bronchus and spilling into right main bronchus. ***(Chapter 82)***

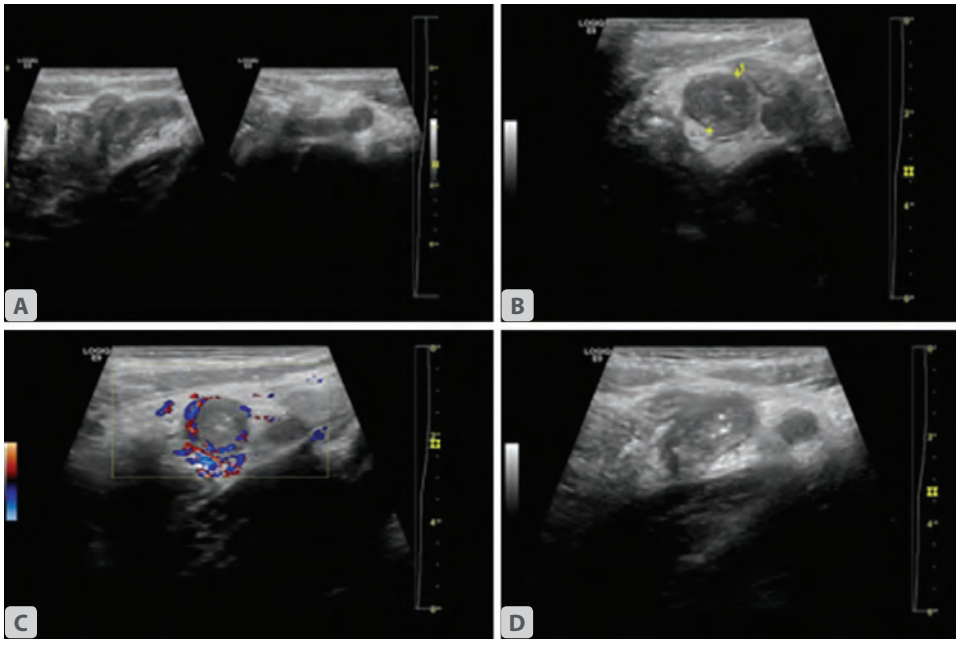
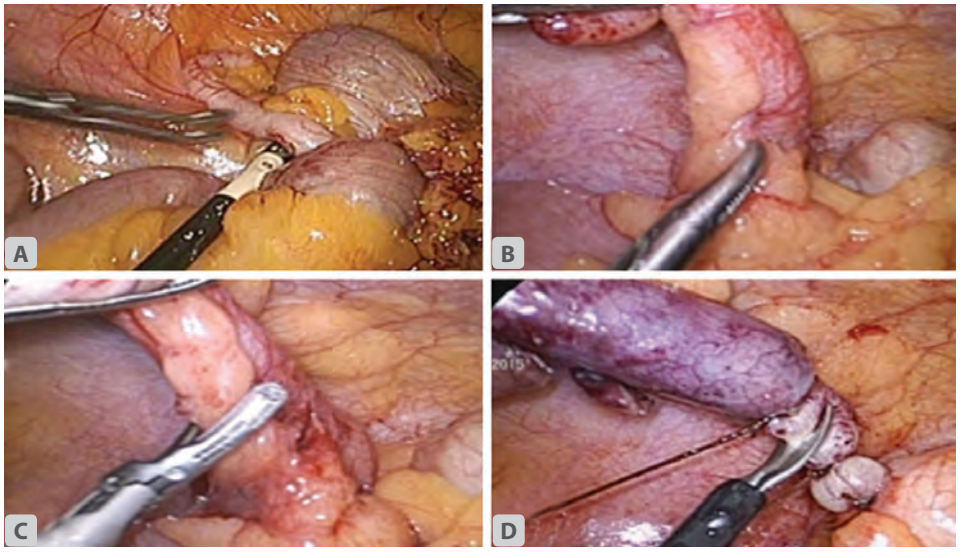
FIG. 1: Grade 4 clubbing of all nails of the hands. ***(Chapter 83)***

FIG. 2: Peripheral cyanosis in one of the hands. ***(Chapter 83)***

PLATE 11

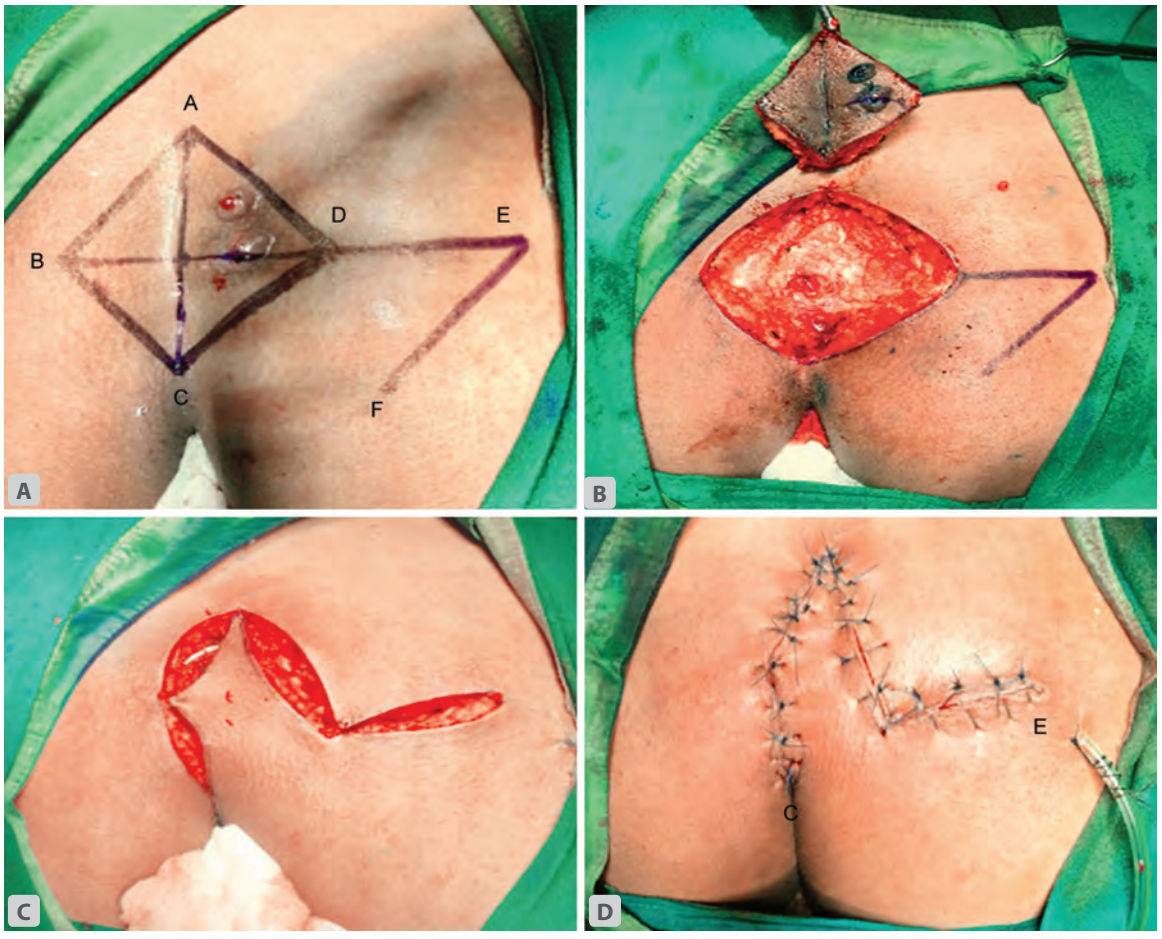


FIGS. 2A TO D: Ultrasonography findings of acute appendicitis. (A) Thickening of the appendiceal wall and increased blood flow (ring of fire appearance); (B) Loss of wall compressibility; (C) Increased echogenicity of the surrounding fat; (D) Loculated pericecal fluid. ***(Chapter 103)***



FIGS. 4A TO D: Laparoscopic appendectomy. (A) Localization; (B) Dissection of mesoappendix; (C) Harmonizing mesoappendix; (D) Endo-loop ligation and division of appendix. ***(Chapter 103)***

PLATE 12



FIGS. 4A TO D: (A) Rhomboid excision with Limberg flap. (B) Rhomboid area to be excised and flap to be taken is marked. (C) Rhomboid excision of diseased tissue is done. (D) Flap created and fixed at points A, B, C, D suction drain in situ. ***(Chapter 104)***

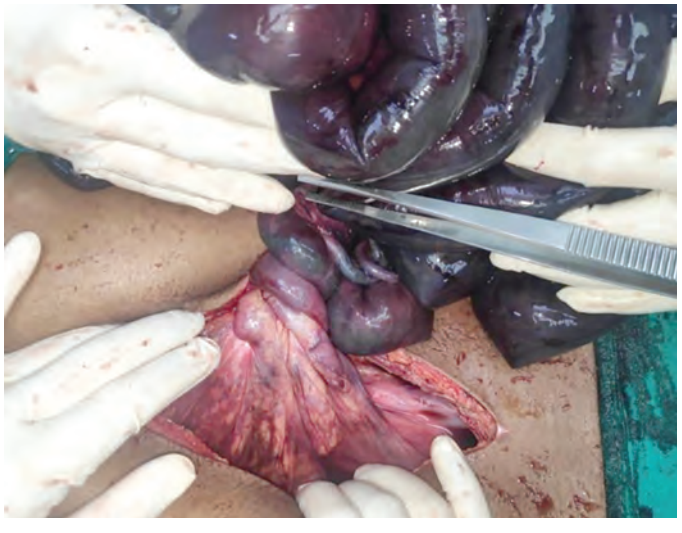


FIG. 4: Surgical resection of gangrenous ischemic bowel. ***(Chapter 105)***

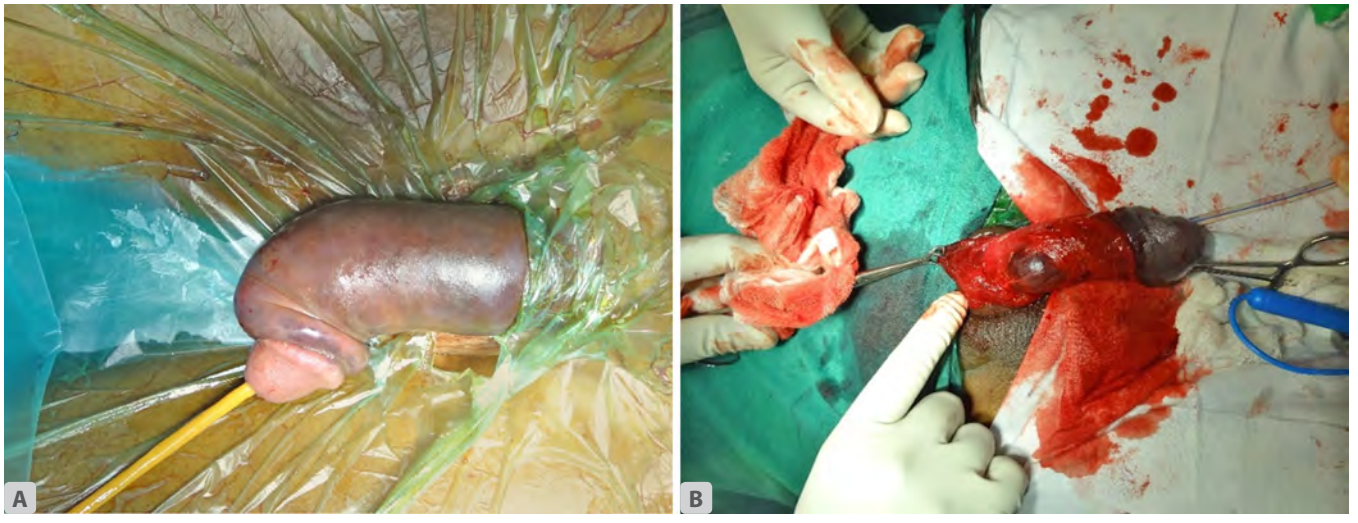
Courtesy: Dr Ashok Puranik.

FIG. 3: Phimosis in a child. ***(Chapter 113)***

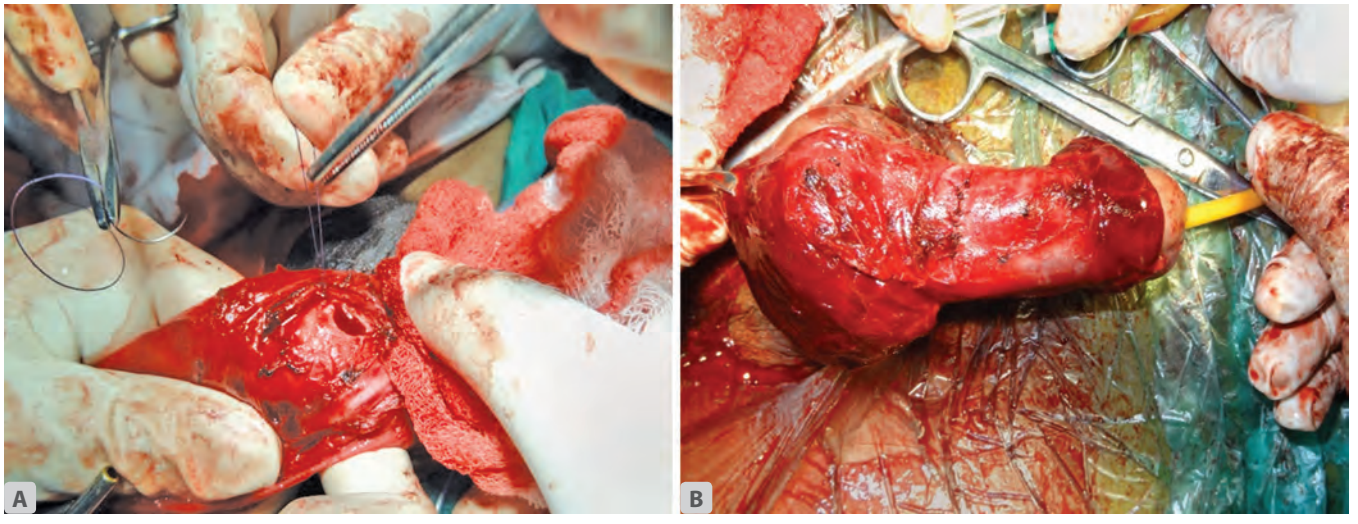
PLATE 13

FIG. 4: Phimosis in an adult. ***(Chapter 113)***

FIG. 5: Paraphimosis in a child. ***(Chapter 113)***



FIGS. 6A AND B: Examination of penile fracture. (A) Eggplant appearance of penile fracture; (B) Hematoma on ventrolateral aspect. ***(Chapter 113)***



FIGS. 7A AND B: Surgical correction of penile fracture. (A) Closure of tunica tear in process; (B) After completion of closure. ***(Chapter 113)***

PLATE 14

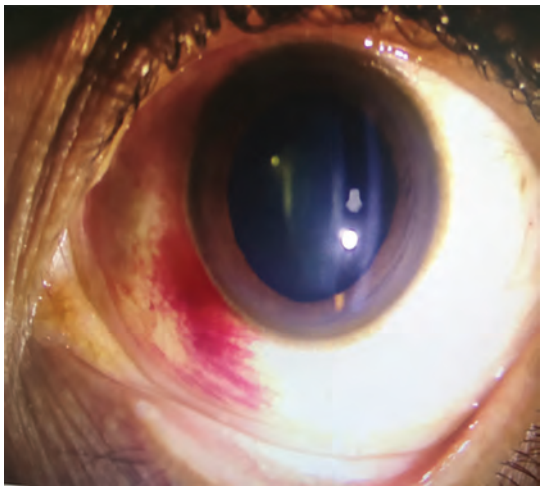


FIG. 1: Subconjunctival hemorrhage. ***(Chapter 133)***

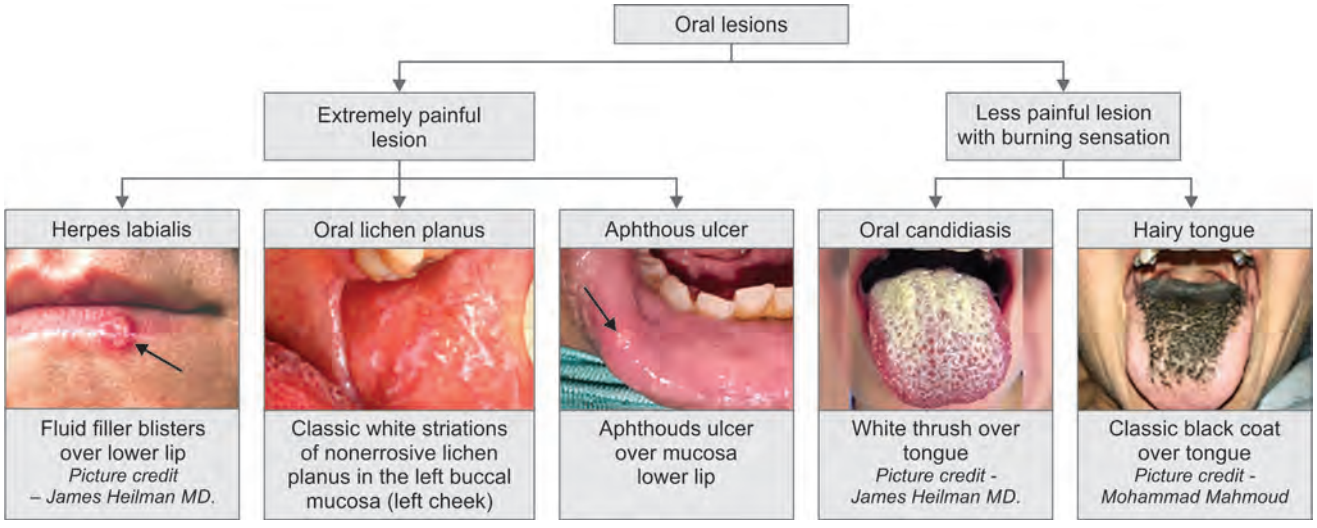
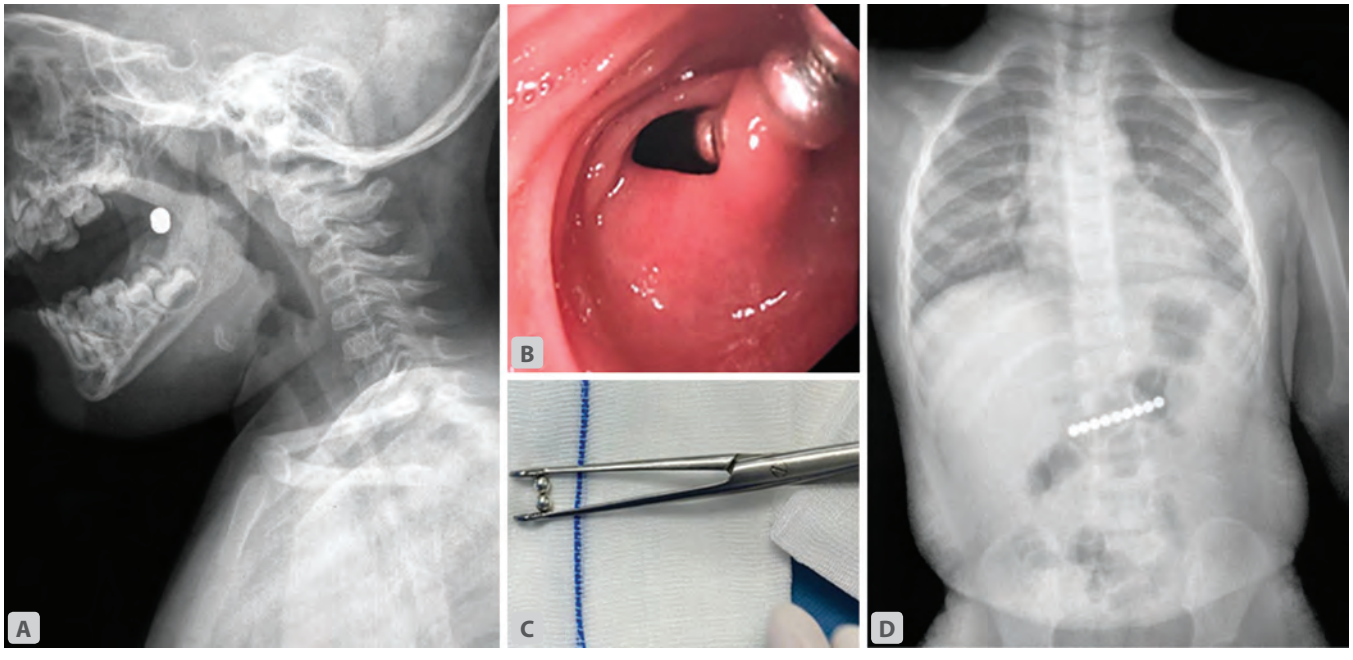
PLATE 17



Oral lesions
Extremely painful lesion
Less painful lesion with burning sensation
Herpes labialis
Oral lichen planus
Aphthous ulcer
Oral candidiasis
Hairy tongue
Fluid filler blisters over lower lip
Picture credit – James Heilman MD.
Classic white striations of nonerrosive lichen planus in the left buccal mucosa (left cheek)
Aphthouds ulcer over mucosa lower lip
White thrush over tongue
Picture credit - James Heilman MD.
Classic black coat over tongue
Picture credit - Mohammad Mahmoud

FLOWCHART 4: Evaluation of oral lesions. ***(Chapter 137)***



FIGS. 11A TO D: Child who presented after pain and dysarthria after being found playing with magnets. (A) Lateral X-ray revealed two circular and superimposed densities within the oral cavity. (B): Bronchoscopy revealed the patient's uvula to be entrapped between two magnets. (C) Removed spherical magnets. (D) X-ray of the chest and abdomen revealed multiple secondary ingested foreign bodies within the abdomen forming a sequential chain within the intestine. ***(Chapter 138)***

PLATE 18

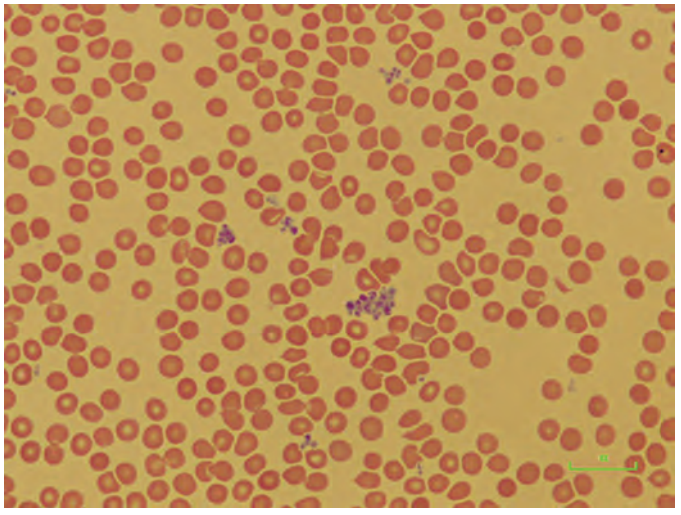


FIG. 1: Platelet clumping. Not an emergency but can give an erroneously low platelet count. ***(Chapter 140)***

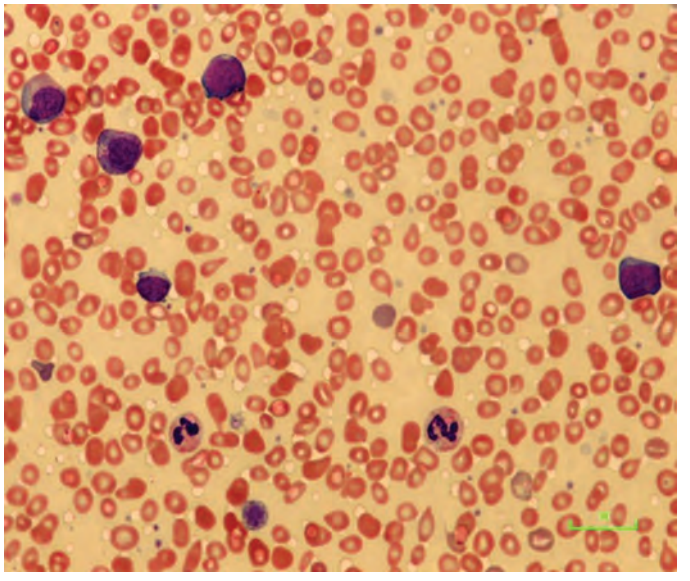

FIG. 1: Slide of acute myeloid leukemia, myelocytes, myeloid blast, dysplastic giant platelets, and polychromasia. ***(Chapter 141)***

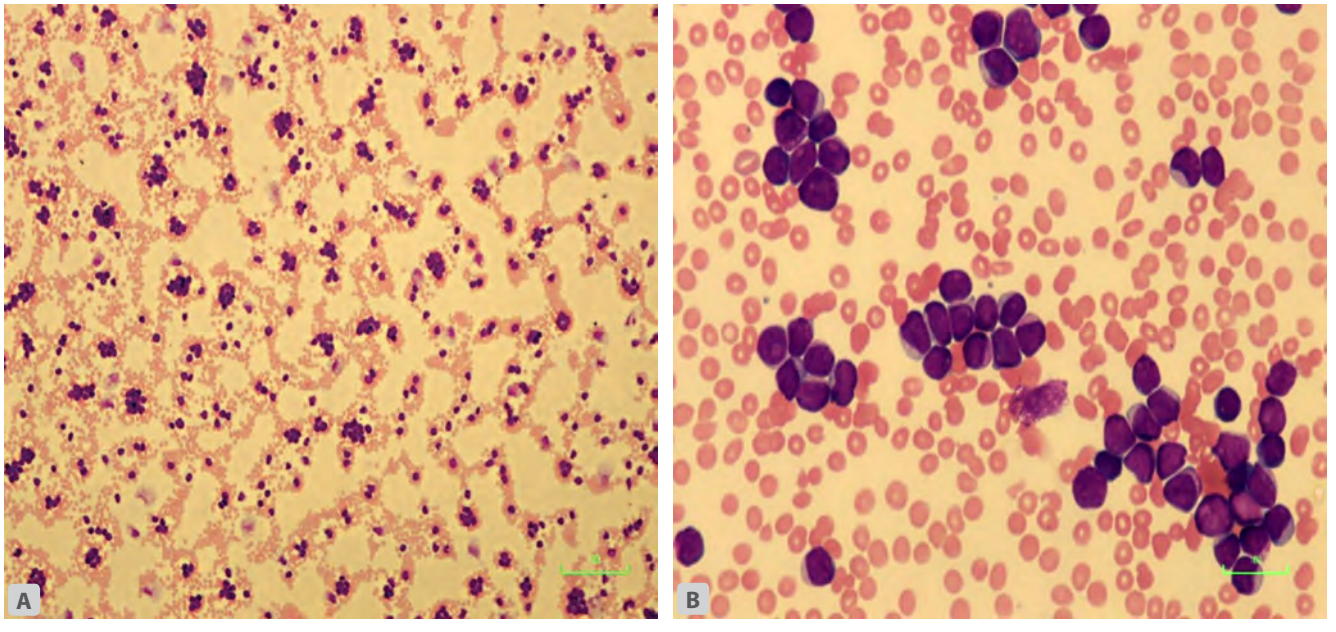


FIGS. 2A AND B: (A) Slide shows hyperleukocytosis in a patient with acute myeloid leukemia (AML). (B) Slide shows myeloid blasts seen in the AML with hyperleukocytosis. Myeloid blasts contain granules, best seen in the highlighted cells. ***(Chapter 141)***

PLATE 19

(Chapter 148)

TABLE 1: Primary skin lesions.

S. No.	*Type of lesion*	*Description*	*Example*
1.	Macule	A circumscribed area of skin or mucous membrane different in color or texture from its neighboring tissue, measuring <1 cm in diameter.	
2.	Patch	A circumscribed area of skin or mucous membrane different in color or texture from its neighboring tissue, measuring >1 cm in diameter.	
S. No.	*Type of lesion*	*Description*	*Example*
3.	Papule	A small solid, elevation of the skin <1 cm in diameter.	

Continued

PLATE 20

Continued

4.	Plaque	A solid elevated area of skin >1 cm in diameter, where the horizontal dimensions are more than vertical.	
5.	Nodule	A solid elevated area of skin >1 cm in diameter, which can be observed as an elevation or can be palpated.	
6.	Vesicle	A circumscribed elevated area of skin <1 cm in diameter, containing fluid other than pus.	
S. No.	***Type of lesion***	***Description***	***Example***
7.	Bulla	A circumscribed elevated lesion of >1 cm in diameter containing free fluid other than pus.	

Continued

PLATE 21

Continued

8.	Pustule	A circumscribed area of the skin of any size containing visible purulent exudate.	
9.	Cyst	A closed cavity or sac with an epithelial, endothelial, or membranous lining, containing fluid or semisolid material.	
10.	Wheal	An elevated, evanescent compressible area due to dermal edema. It is pale and often surrounded by a dermal flare.	

PLATE 22

(Chapter 148)

TABLE 2: Secondary skin lesion.

S. No.	*Type of lesion*	*Description*	*Example*
1.	Erosion	Loss of whole or part of the epidermis, but with the dermis left intact, and which heals without scarring.	
2.	Ulcer	A breach in continuity of the epidermis and at least a part of dermis, associated with necrosis of tissue and which heals with scarring.	
3.	Excoriation	Loss of substance of skin produced by scratching (linear erosions).	
4.	Scale	Visible exfoliation of skin.	

Continued

PLATE 23

Continued

S. No.	Type of lesion	Description	Example
5.	Crust	Accumulation of dried up exudate, secretion, or hemorrhage on the skin surface as a result of its disruption.	
6.	Scar	A visible alteration in the appearance of the skin due to fibrous tissue replacing normal tissues destroyed by disease or injury.	
7.	Lichenification	Thickening of the skin with exaggeration of its normal marking often as a result of chronic scratching or rubbing.	
8.	Sclerosis	Circumscribed or diffuse hardening of skin usually due to fibrosis.	

PLATE 24

(Chapter 148)

TABLE 3: Special lesions.

Special lesions		
Burrow	A passage or a tunnel in the skin that houses a parasite, e.g., scabies.	
Comedones	A plug of keratin or a sebum in a dilated pilosebaceous orifice, e.g., acne vulgaris.	
Purpura	Discoloration of skin due to extravasation of blood. • If >2 cm in diameter—ecchymosis • If <2 cm (pin point)—petechiae • If linear, it is called vibex	
Telangiectasias	Permanent dilatation of capillaries.	
Continued

PLATE 25

Continued

Special lesions		
Fissure	A small linear gap or slit in the skin surface.	
Sinus	A closed cavity or channel that permits the escape of pus or fluid.	
Milium	A tiny white superficial cyst with an epidermal lining containing keratin.	

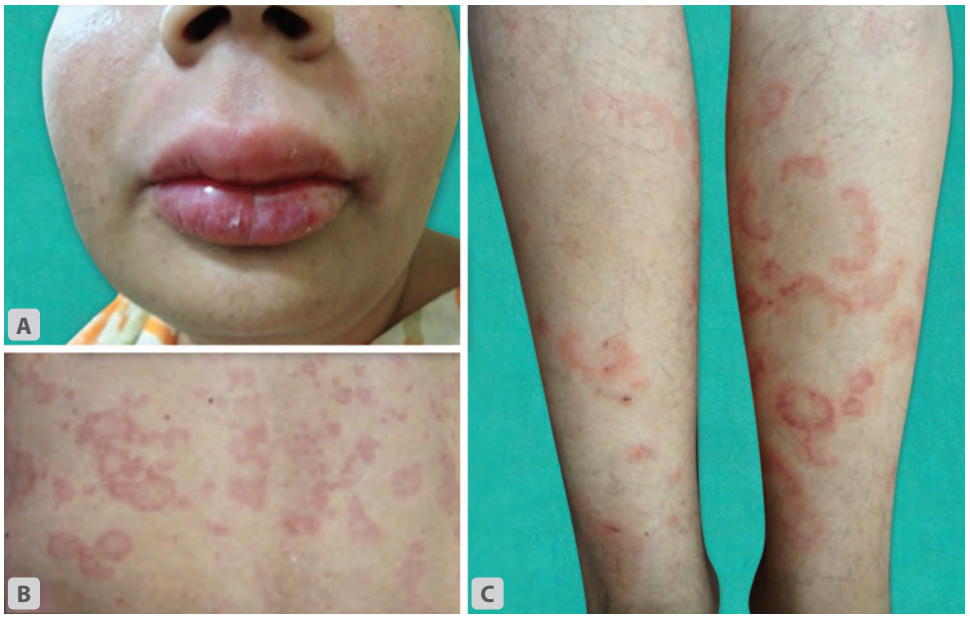
PLATE 26

FIGS. 1A TO C: (A and B) Epidermal involvement in Stevens–Johnson syndrome (SJS); (C) Toxic epidermal necrolysis (TEN). ***(Chapter 149)***

FIG. 2: Pyoderma gangrenosum. ***(Chapter 149)***

FIGS. 3A AND B: Necrotizing fasciitis. ***(Chapter 149)***

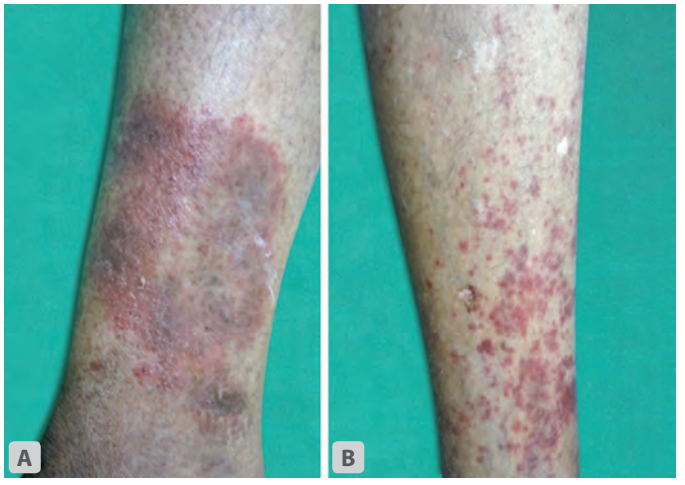
PLATE 27



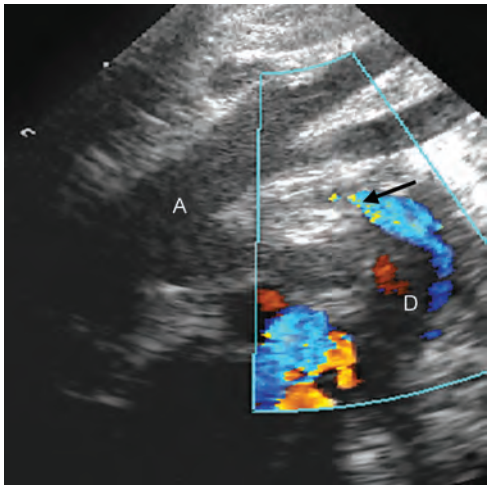
FIGS. 4A TO C: (A) Angioedema; (B and C) Urticaria. ***(Chapter 149)***

FIGS. 5A AND B: (A) Pemphigus vulgaris; (B) Pemphigus fallacious. ***(Chapter 149)***

PLATE 28



FIGS. 6A AND B: Vasculitis. ***(Chapter 149)***



(AAO: ascending aorta, DAO: descending aorta)

FIG. 3: Echocardiography with color flow mapping of a neonate with aortic arch interruption, restrictive PDA and LV dysfunction. Suprasternal long axis view showing arch interruption, small PDA (black arrow) filling descending aorta. ***(Chapter 170)***

FIGS. 7A TO D: Psoriasis. ***(Chapter 149)***

PLATE 29

FIGS. 1A AND B: Pediatric oral and dental trauma. (A) 12 years of age female that fell while riding her bike and sustained oral/dental injuries. (B) 3 years of age male that fell onto a concrete sidewalk and sustained a dental injury. ***(Chapter 173)***

FIG. 3: Frenulum laceration. 18-month-old male that fell and sustained frenulum laceration. No intervention was required and he was discharged to home. ***(Chapter 173)***

FIGS. 4A AND B: Tongue laceration. (A) 8 years of age male who sustained tongue laceration while jumping on a trampoline. (B) Laceration repaired with horizontal mattress sutures in the ED with procedural sedation. ***(Chapter 173)***

PLATE 30

FIG. 1: Miliaria rubra. ***(Chapter 174)***

FIG. 2: Neonatal acne. ***(Chapter 174)***

FIG. 3: Transient pustular melanosis. ***(Chapter 174)***

FIG. 4: Infantile acropustulosis. ***(Chapter 174)***

FIG. 5: Erythema toxicum. ***(Chapter 174)***

FIG. 6: Seborrheic dermatitis. ***(Chapter 174)***

PLATE 31

FIG. 7: Oral candidiasis. ***(Chapter 174)***

FIG. 8: Irritant diaper dermatitis. ***(Chapter 174)***

FIG. 9: *Candida* diaper rash. ***(Chapter 174)***

FIG. 10: Drool rash. ***(Chapter 174)***

PLATE 32

FIGS. 11A TO E: Infantile scabies. ***(Chapter 174)***

FIG. 12: Infantile eczema. ***(Chapter 174)***

FIG. 13. Mongolian spot. ***(Chapter 174)***

PLATE 33

FIG. 14: Neurofibromatosis with axillary freckling (Crowe sign). ***(Chapter 174)***

FIG. 17. Cutis marmorata. ***(Chapter 174)***

FIG. 15: Darier sign for urticaria pigmentosa. ***(Chapter 174)***

FIG. 18: Harlequin color change. ***(Chapter 174)***

FIG. 16: Incontinentia pigmenti. ***(Chapter 174)***

FIG. 19: Nevus flammeus. ***(Chapter 174)***

PLATE 34

FIG. 20: Strawberry hemangioma. ***(Chapter 174)***

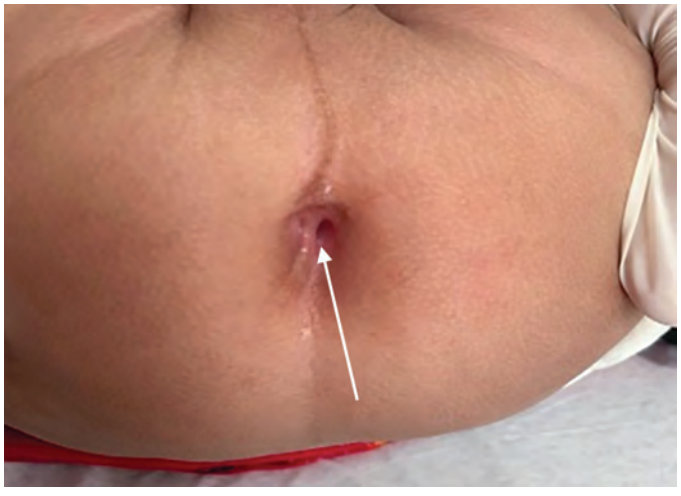


FIG. 3: Anal dimple—anorectal malformation (ARM). ***(Chapter 176)***

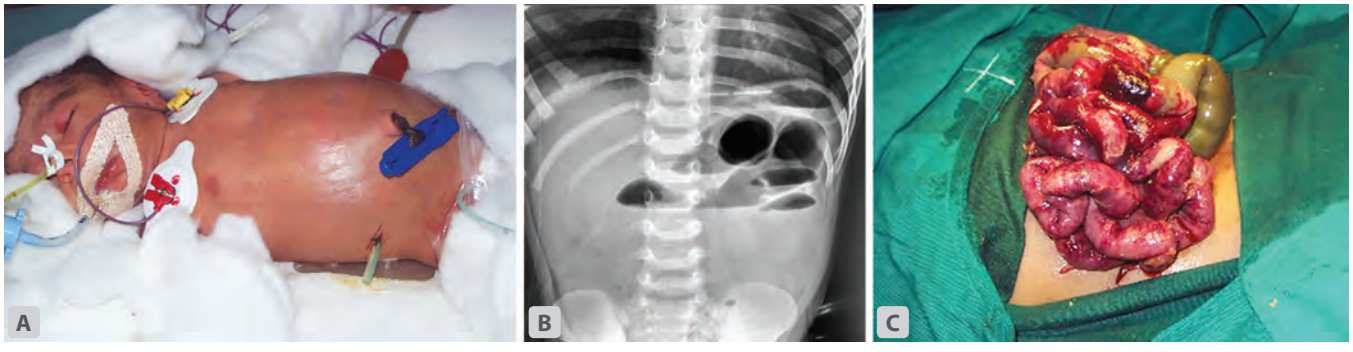
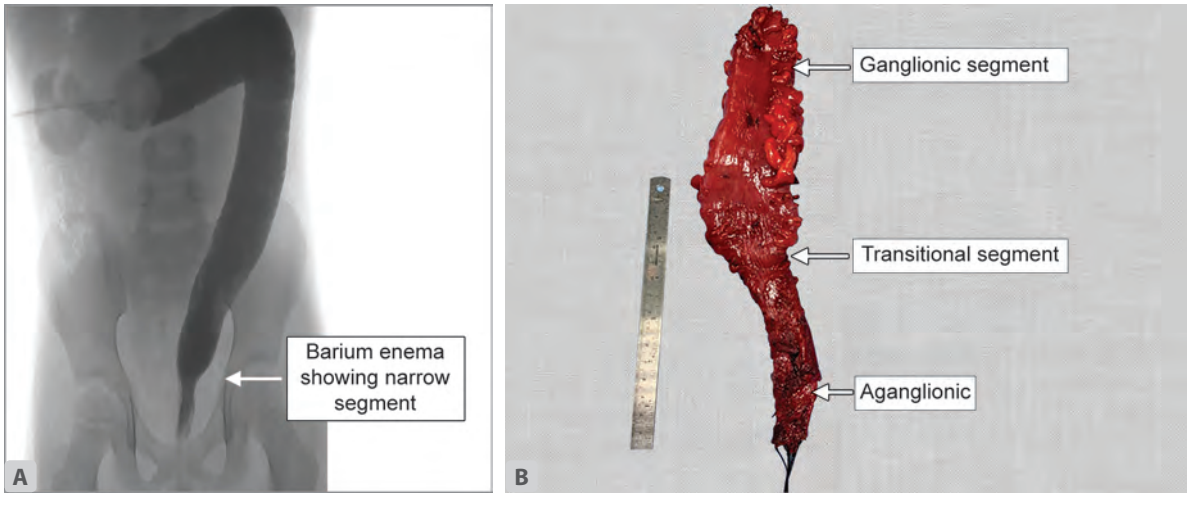
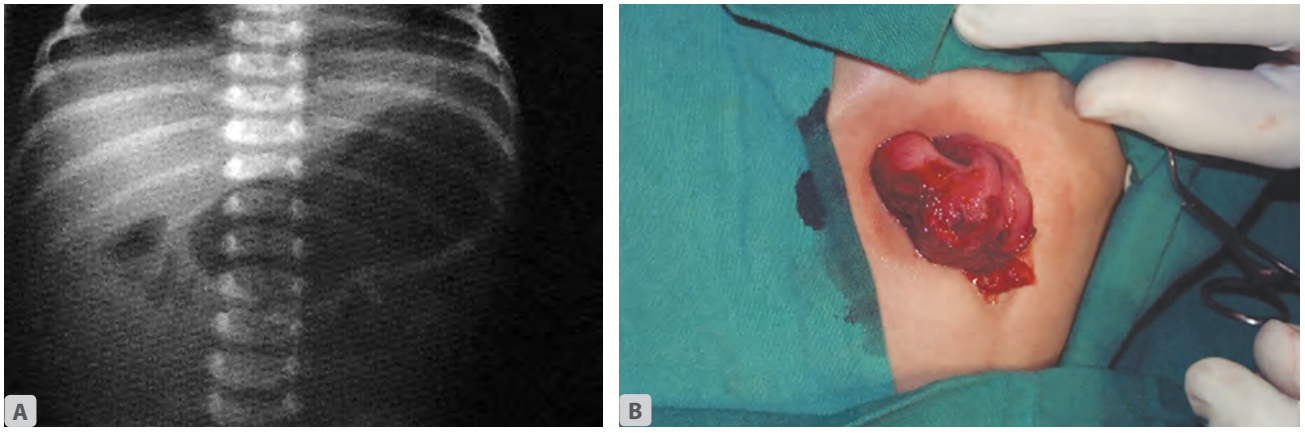


FIGS. 1A TO C: (A) Clinical picture of neonatal necrotizing enterocolitis (NNEC); (B) X-ray abdomen showing multiple air fluid levels; (C) intestinal gangrene ***(Chapter 176)***

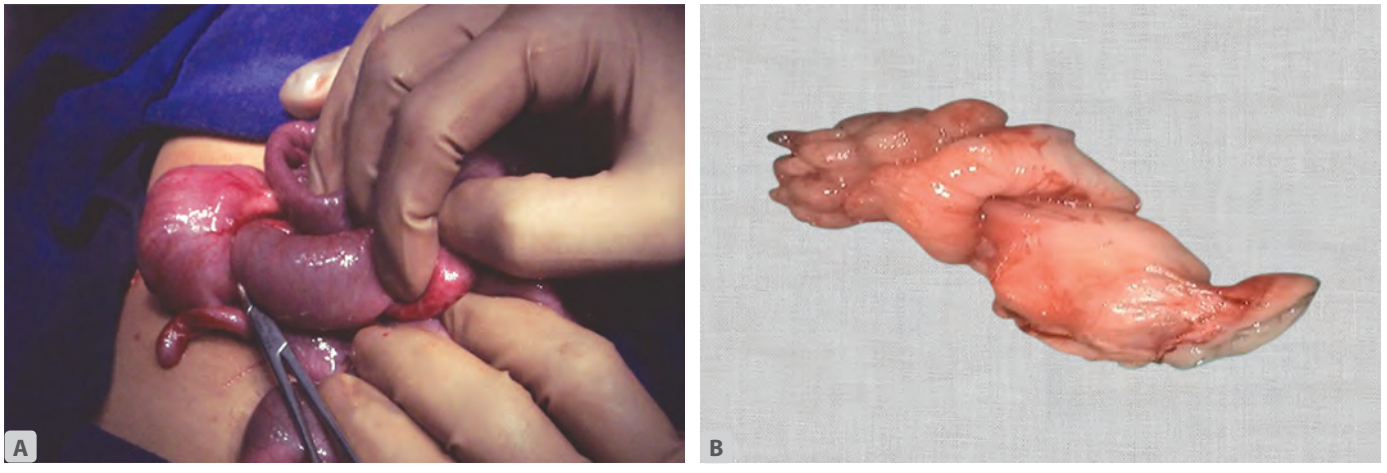


FIGS. 4A AND B: (A) Barium study in Hirschsprung's disease; (B) intraoperative Hirschsprung's specimen. ***(Chapter 176)***

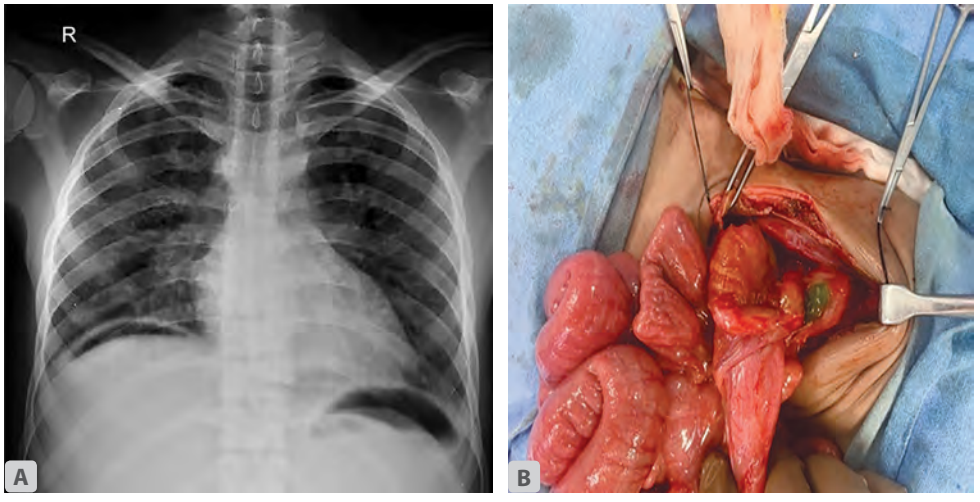
PLATE 35



FIGS. 5A AND B: (A) X-ray pyloric stenosis; **(**B**)** intraoperative specimen pyloric stenosis. ***(Chapter 176)***

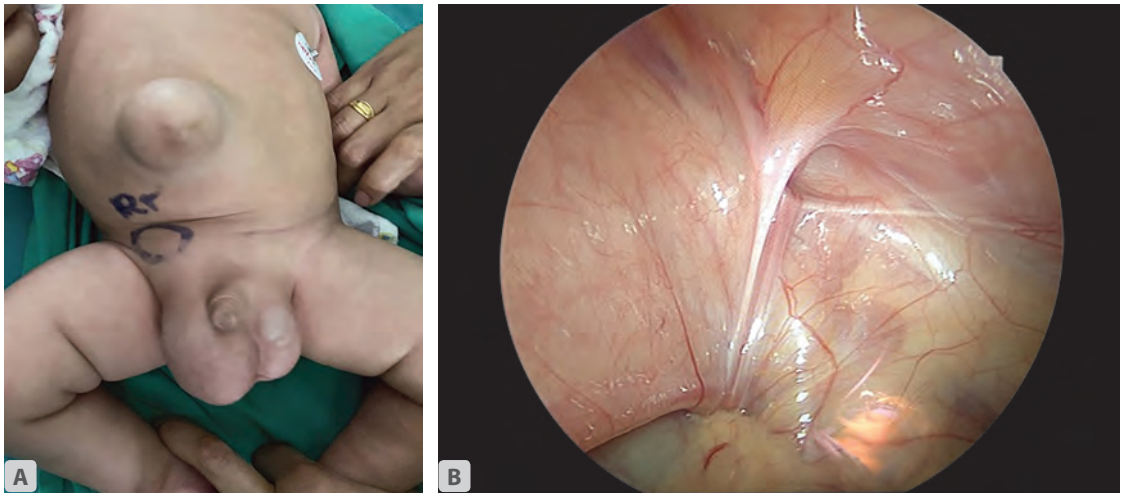


FIGS. 6A AND B: (A) Intussusception; (B) resected specimen. ***(Chapter 176)***



FIGS. 7A AND B: (A) X-ray showing air under the diaphragm; (B) Intestinal perforation. ***(Chapter 176)***

PLATE 36



FIGS. 8A AND B: (A) Irreducible swelling right inguinal and umbilical hernia; (B) laparoscopic correction. ***(Chapter 176)***

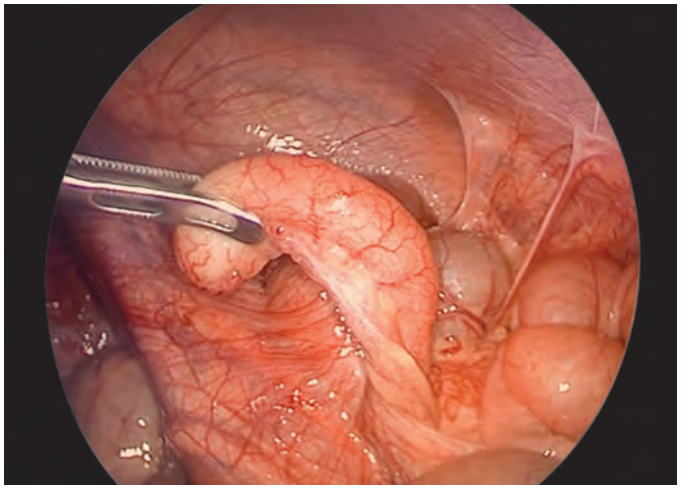


FIG. 10: Appendix (laparoscopic view). ***(Chapter 176)***

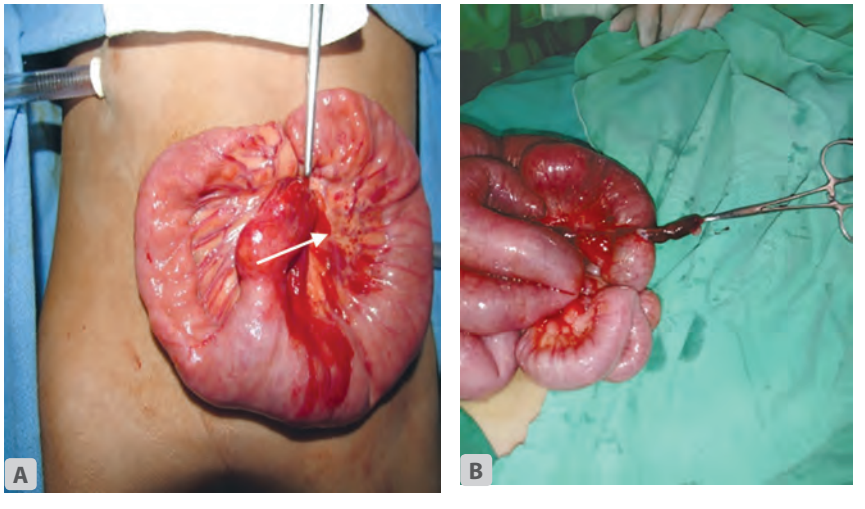

FIGS. 11A AND B: (A) Meckel's diverticulum; (B) Meckel's gangrenous. ***(Chapter 176)***

PLATE 37

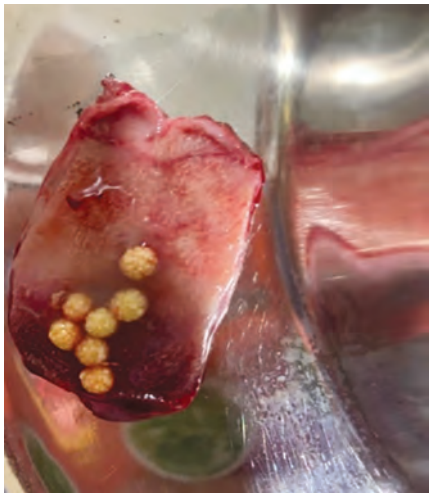

FIG. 12: Gallstones. ***(Chapter 176)***

FIG. 4: *Physostigma venenosum*—calabar bean. ***(Chapter 200)***

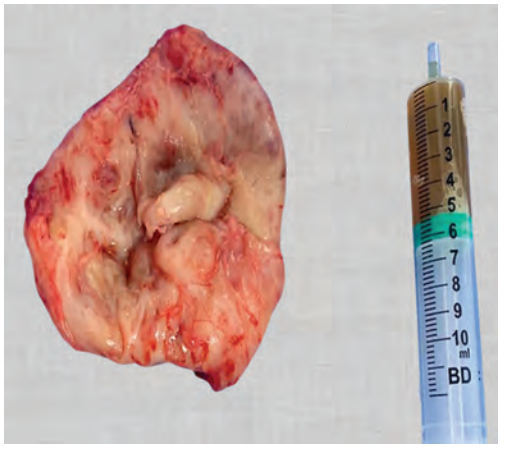

FIG. 14: Mesenteric cyst. ***(Chapter 176)***

FIG. 1: *Thevetia peruviana* (yellow oleander). ***(Chapter 215)***
Courtesy: Avighna Richhariya.

FIG. 3: Greenish frothy fluid oozing out of mouth and nose—dichlorvos poisoning. ***(Chapter 200)***
Courtesy: Dr Swapnil Agarwal.

FIG. 2: *Nerium odorum* (pink oleander). ***(Chapter 215)***
Courtesy: Avighna Richhariya.

PLATE 38

FIG. 2: Septal hematoma. ***(Chapter 222)***

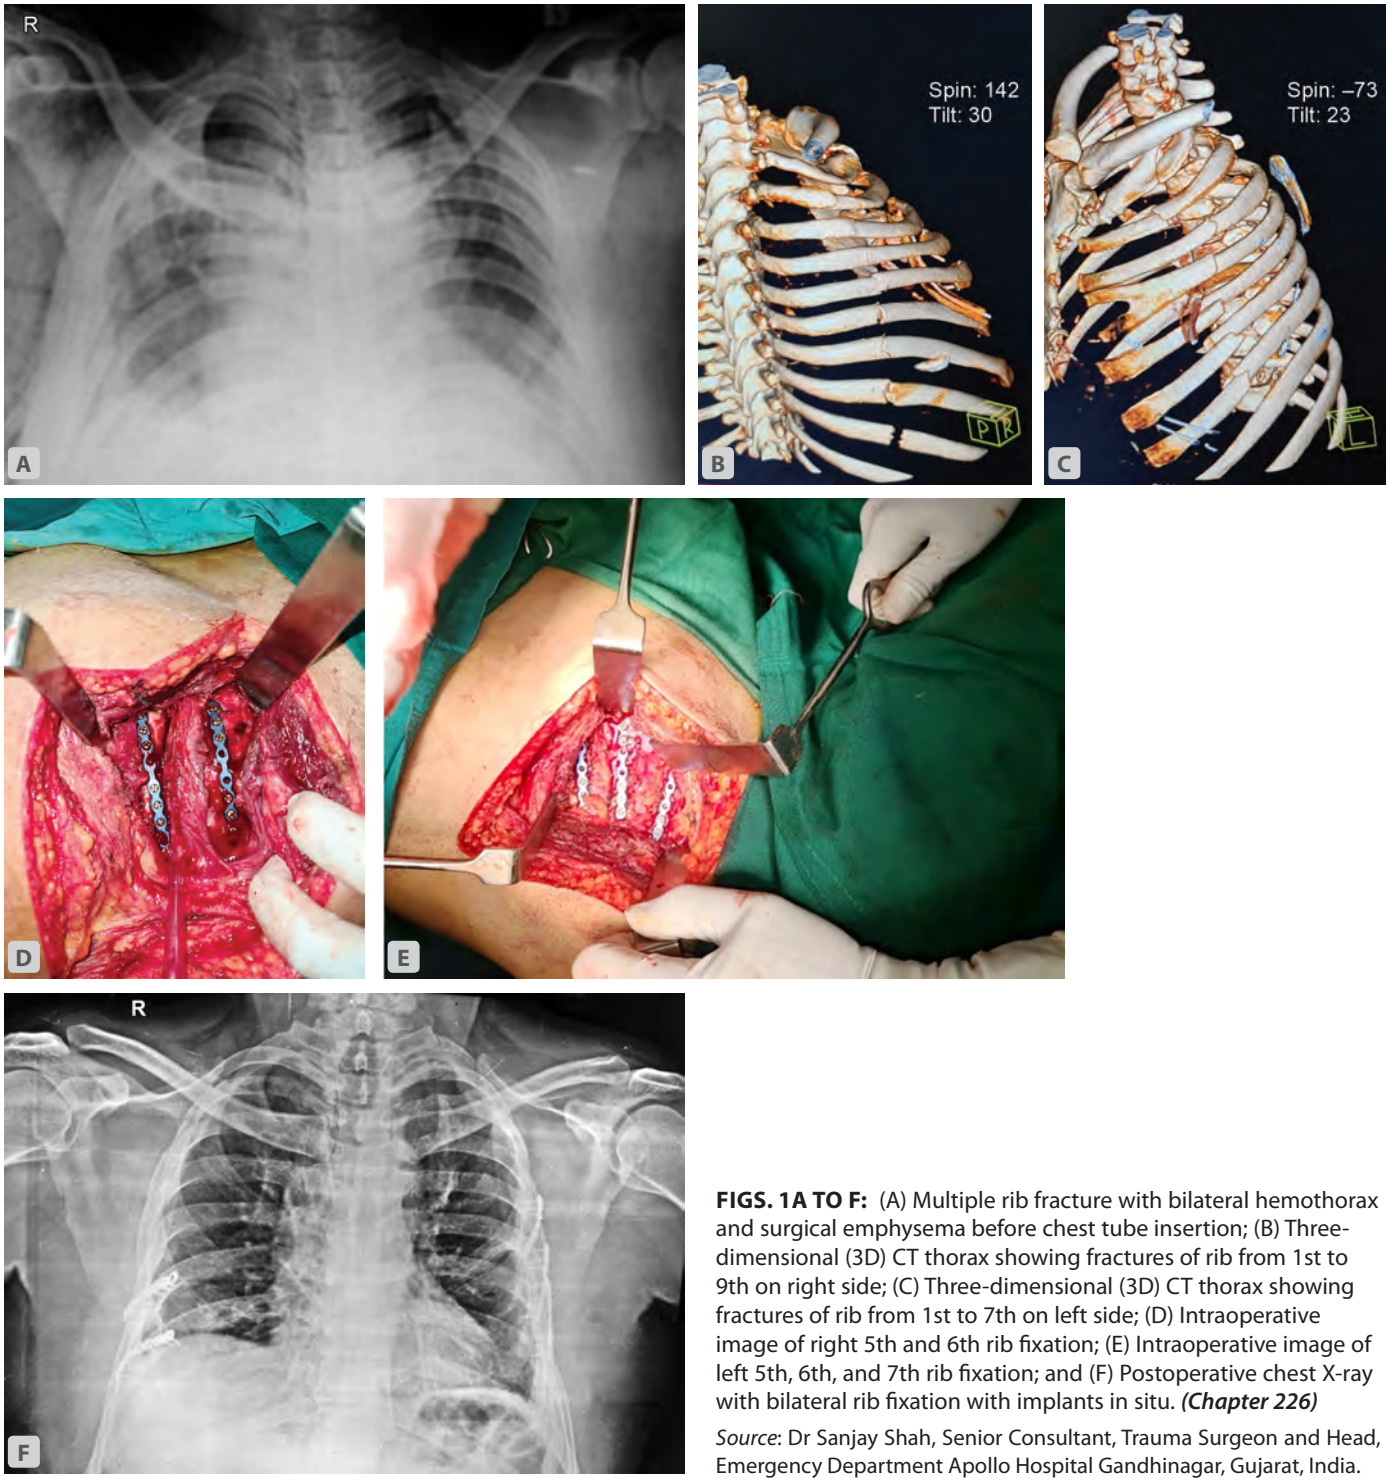
FIG. 4: Hemotympanum. ***(Chapter 222)***

FIG. 13: Laceration of the eyelid. ***(Chapter 222)***

FIG. 12: Periorbital edema. ***(Chapter 222)***

FIG. 14: Laceration of the tongue. ***(Chapter 222)***

PLATE 39

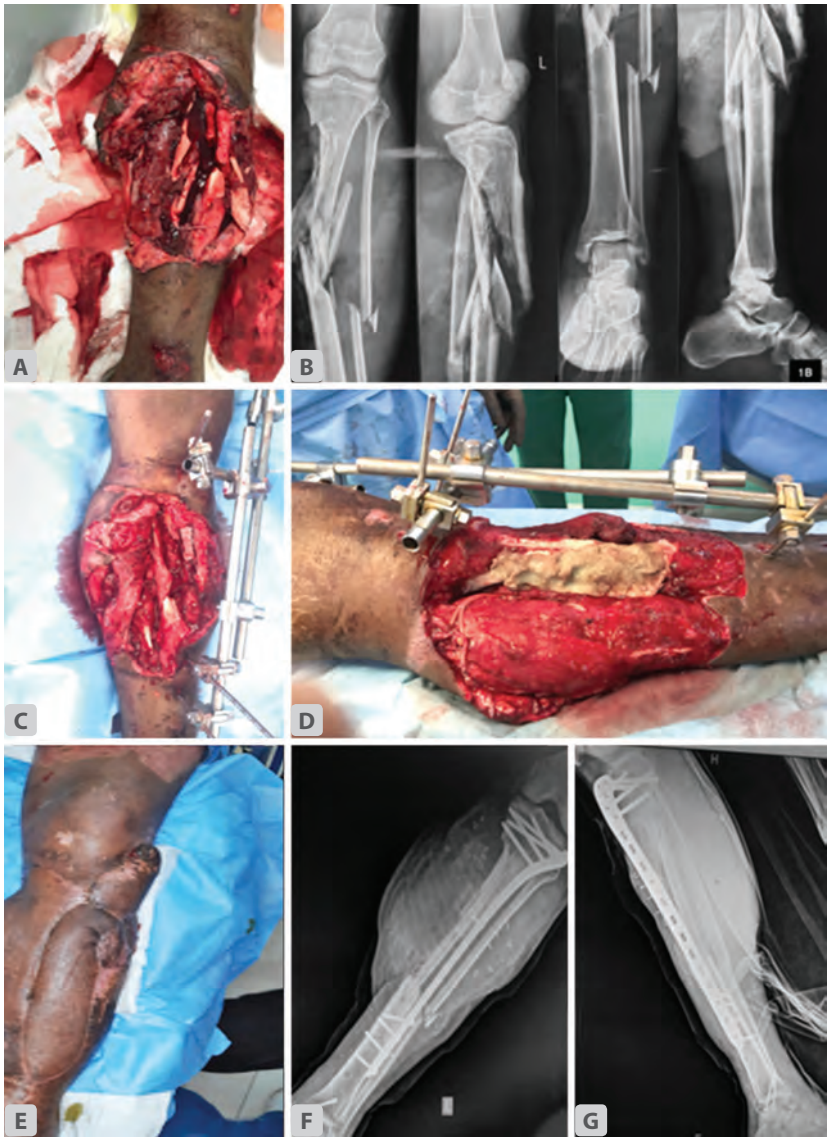


FIGS. 1A TO F: (A) Multiple rib fracture with bilateral hemothorax and surgical emphysema before chest tube insertion; (B) Three-dimensional (3D) CT thorax showing fractures of rib from 1st to 9th on right side; (C) Three-dimensional (3D) CT thorax showing fractures of rib from 1st to 7th on left side; (D) Intraoperative image of right 5th and 6th rib fixation; (E) Intraoperative image of left 5th, 6th, and 7th rib fixation; and (F) Postoperative chest X-ray with bilateral rib fixation with implants in situ. ***(Chapter 226)***

Source: Dr Sanjay Shah, Senior Consultant, Trauma Surgeon and Head, Emergency Department Apollo Hospital Gandhinagar, Gujarat, India.

PLATE 40

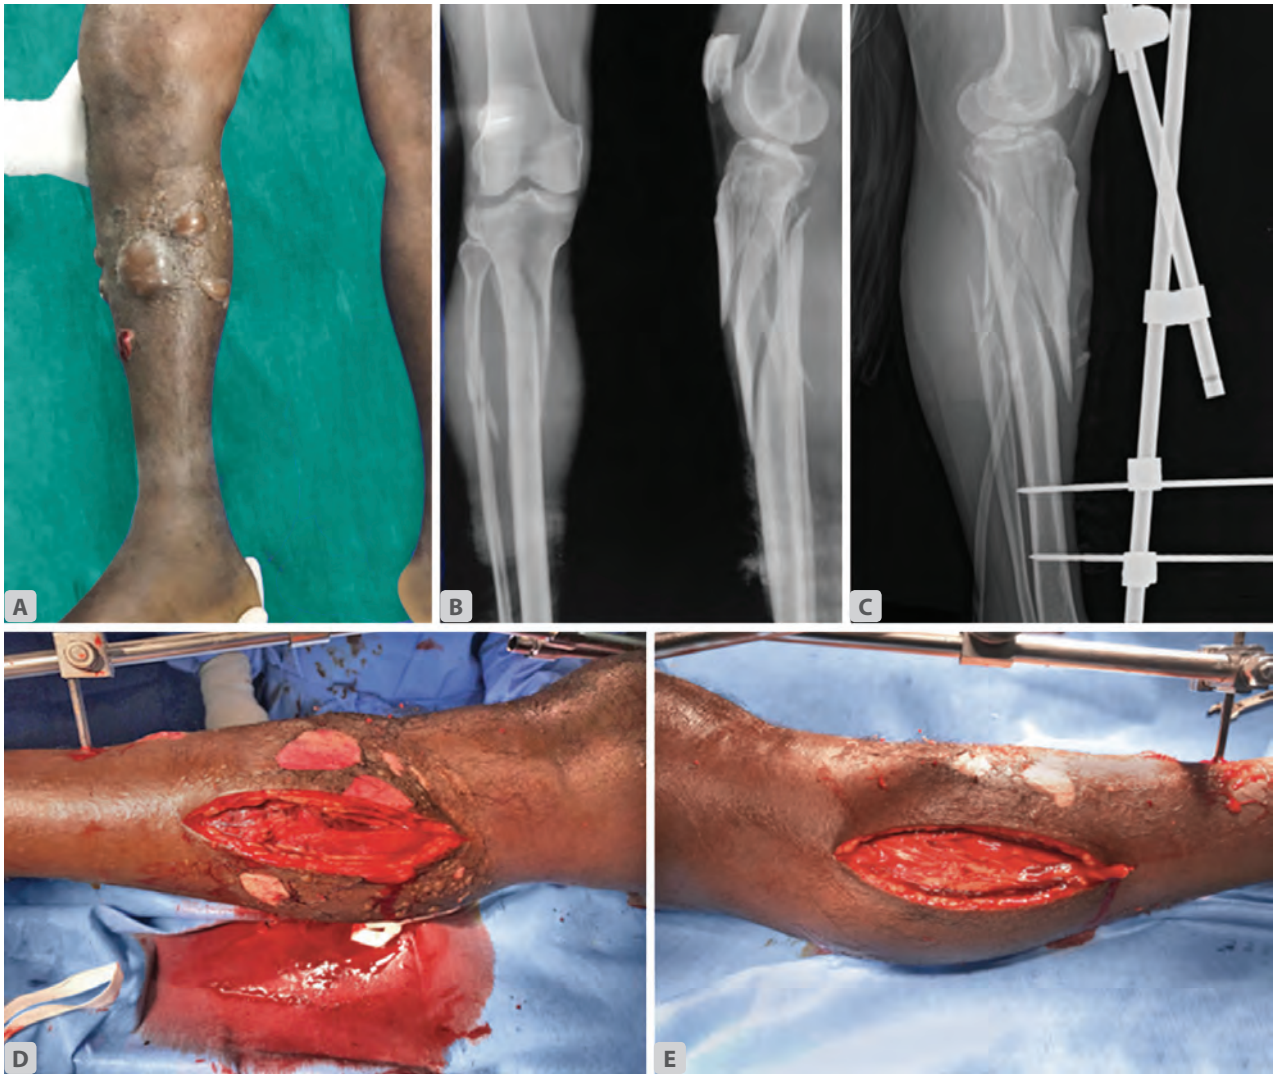
FIG. 1: Visible external injury in abdominal trauma. ***(Chapter 227)***



FIGS. 1A TO G: (A and B) Severely mangled extremity with comminuted fracture; (C) Clinical picture after thorough debridement and knee spanning external fixator; (D) Bone loss spaced with antibiotic bone cement; (E) Post soft-tissue reconstruction; (F and G) X-rays showing good incorporation of the vascularized fibular graft. Compartment pressure measurement should be done in the case of comatose patients. ***(Chapter 229)***

Courtesy: Dr Kesavam.

PLATE 41



FIGS. 2A TO E: (A and B) Right proximal tibial fracture with impending compartment syndrome; (C to E) Application of spanning external fixator, two incision lower limb compartment release. ***(Chapter 229)***

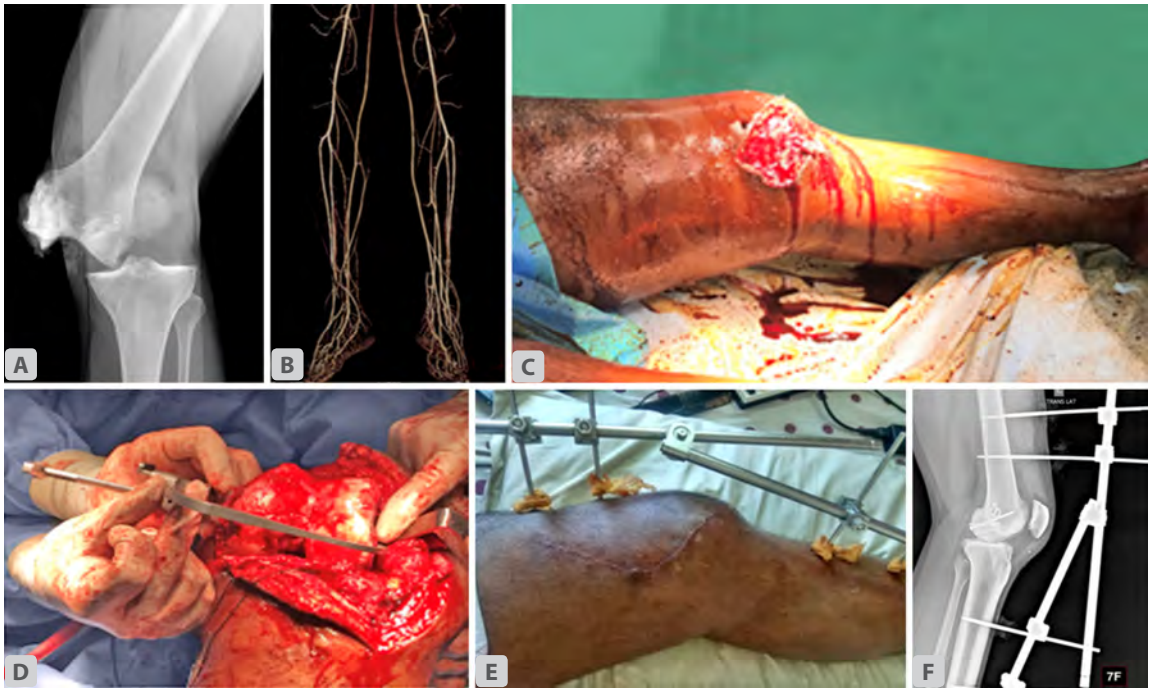
Courtesy: Dr Kesavam.

PLATE 42

FIGS. 3A TO F: (A) Left arm-twisting injury while trying to bend the iron rod in the machine. Note the broken arm encircled around the iron rod. (B) After a thorough wash. (C) Dressed and splinted in extension. (D to F) X-rays are taken at the bedside after proper splinting. ***(Chapter 229)***

Courtesy: Dr Kesavan and Dr Selvaseetharaman.

PLATE 43



FIGS. 7A TO F: (A) X-ray showing medial knee dislocation. Also note the button over the lateral femoral condyle. (B) Normal lower limb arteriogram. (C and D) Intraoperative picture showing the open wound. The wound extended for fracture fixation and ligament reconstruction. Also, knee spanning external fixation is placed to secure the reduction. (E) Healed wound with ex fix in situ. (F) Post ligamentous reconstruction X-ray lateral view showing ex fix in place. ***(Chapter 229)***

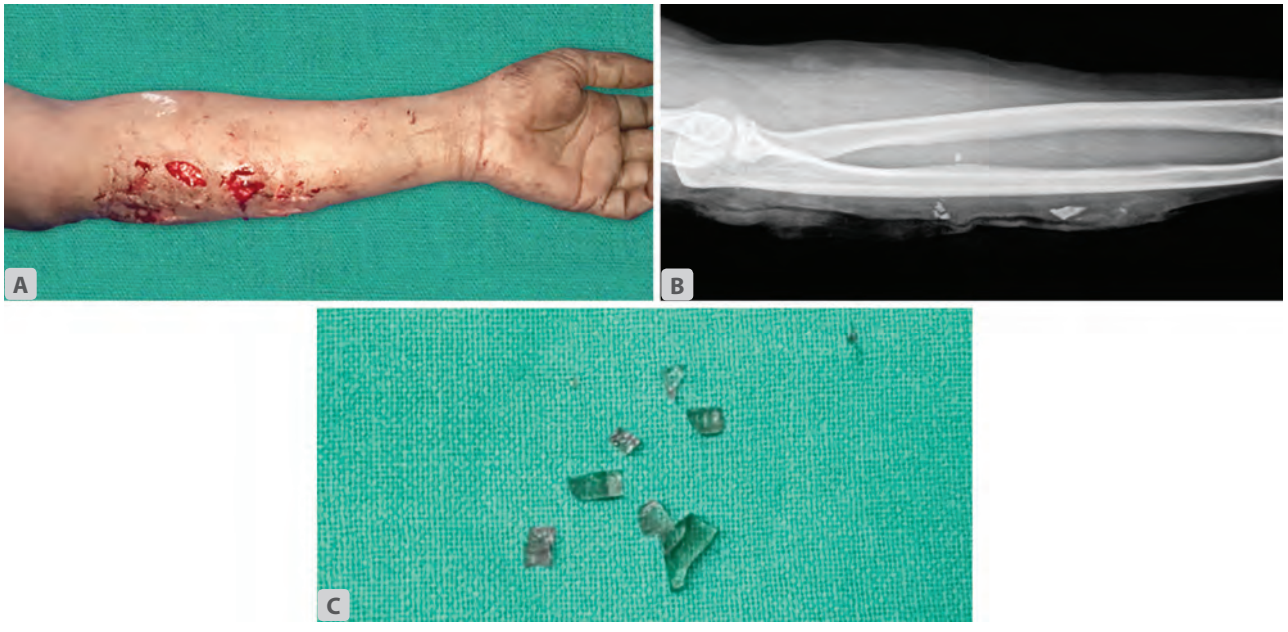
Courtesy: Dr Ajith Yadav.

FIG. 1: Clean lacerated wound on the forehead. ***(Chapter 236)***

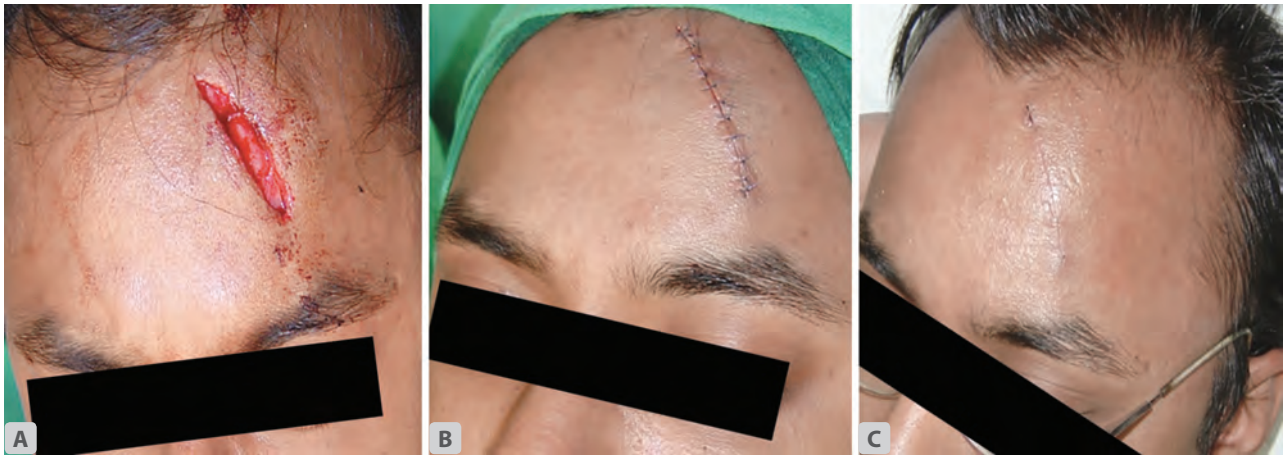
FIG. 2: Complicated laceration of the face. ***(Chapter 236)***

PLATE 44

FIG. 3: Post-traumatic tattooing due to inadequate removal of foreign bodies. ***(Chapter 236)***



FIGS. 4A TO C: (A) Patient involved in road traffic accident with multiple cut injuries to the forearm with retained glass pieces; (B) X-ray showing multiple radiopaque shadows suggestive of retained glass particles; (C) Multiple glass pieces removed from the wound. ***(Chapter 236)***



FIGS. 5A TO C: (A) Clean lacerated wound of the forehead; (B) Primary closure of the wound; (C) Postoperative results after 4 weeks ***(Chapter 236)***

PLATE 45

FIGS. 1A TO C: Dry cooling for transfer of the amputated part. (A) Finger in a clean plastic bag; (B) Ice in a separate plastic bag; (C) Bag with a finger placed such that the finger does not have direct contact with the ice. ***(Chapter 237)***

FIGS. 2A AND B: (A) Clean lacerated wound of the right eyebrow (no need to shave the hair); (B) Good eyebrow alignment after 1 week. ***(Chapter 237)***

FIGS. 3A AND B: (A) Clean lacerated wound of the forehead and eyebrow; (B) A single stitch taken to align the eyebrow prior to a primary repair of the remaining wound. ***(Chapter 237)***

PLATE 46

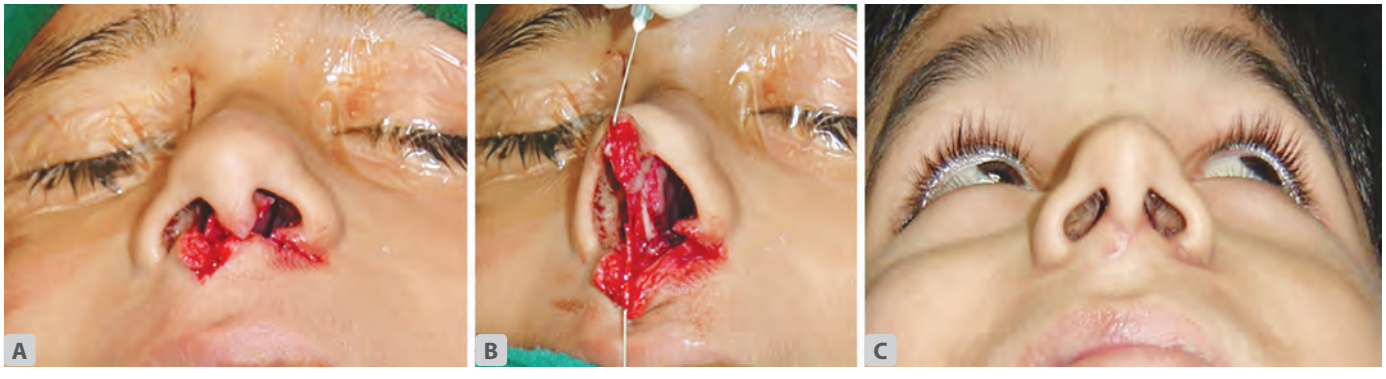
FIGS. 4A AND B: (A) Complex periorbital laceration involving the eyebrow, lid, and lateral canthus; (B) Results after 6 months—careful anatomical alignment maintained during the repair. ***(Chapter 237)***

FIGS. 5A AND B: (A) Complex periorbital injury showing disruption of the medial canthus with nasolacrimal duct injury and facial skin avulsion following a road traffic accident; (B) Late postoperative (6 months) results of a primary repair and fixation of underlying fractures. ***(Chapter 237)***

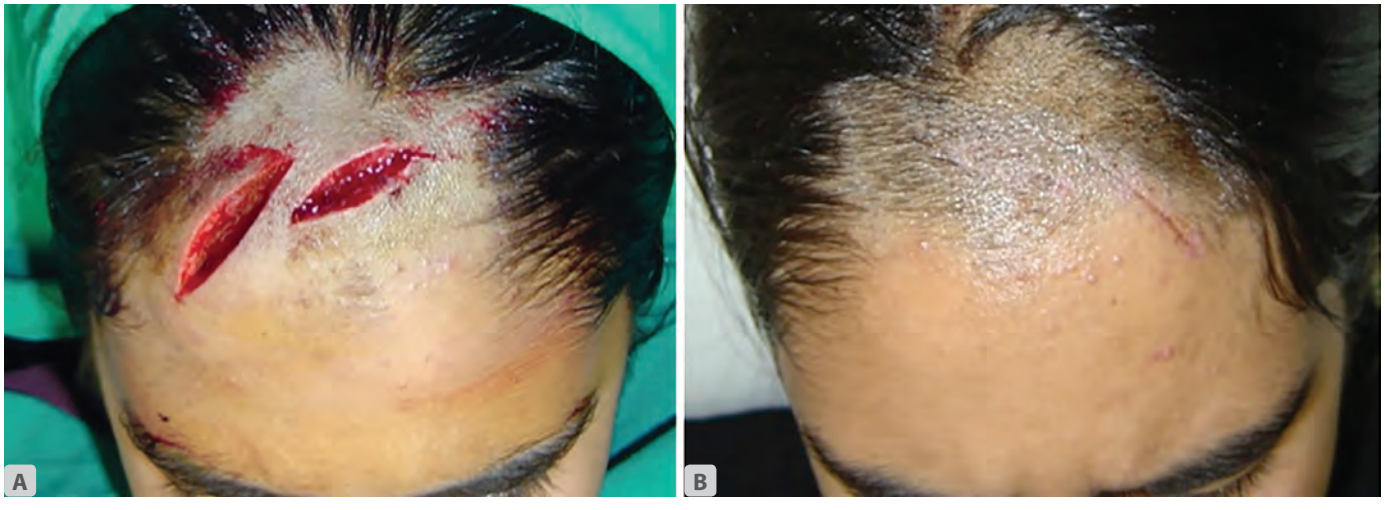
FIG. 6: Poorly stitched oblique cheek laceration with parotid duct injury. The wound was re-explored and the parotid duct repaired. ***(Chapter 237)***

PLATE 47

FIGS. 7A AND B: (A) Complex ear laceration with exposed cartilage; (B) Well-aligned repair with good healing on postoperative day 7. ***(Chapter 237)***



FIGS. 8A TO C: (A) Complicated nasal injury following a fall on a sharp object; (B) Identifying the injured structures—septal cartilage, columella, upper lip, and nasal floor; (C) Postoperative (day 30) picture showing good anatomical alignment. ***(Chapter 237)***



FIGS. 9A AND B: (A) Patient referred from a primary health center with shaved scalp hair (avoid shaving unless grossly contaminated); (B) Wound on postoperative day 10. ***(Chapter 237)***

PLATE 48

FIGS. 10A AND B: (A) Scalp avulsion following a road traffic accident—needed removal of the avulsed skin flap and split skin graft; (B) Postoperative results on day 15. ***(Chapter 237)***

FIGS. 11A AND B: (A) Upper lip clean laceration involving the vermilion border—repaired with careful white roll alignment of the vermillion border; (B) Postoperative day 10 results. ***(Chapter 237)***

FIGS. 12A AND B: (A) Complex lip laceration following a road traffic accident showing a through-and-through avulsion of the lower lip with other facial injuries. A three-layer repair (mucosa, muscle, and skin); (B) Results on postoperative day 30. ***(Chapter 237)***

PLATE 49

FIGS. 13A AND B: (A) Deep through-and-through laceration of the tongue that was repaired by a layered closure with a 5-0 Vicryl; (B) Intraoperative results. ***(Chapter 237)***

FIGS. 14A TO D: (A) Patient reported with a facial nerve palsy following facial laceration repair at a primary care unit; (B) Operative picture showing the exploration of the wound and identification of the facial nerve injury; (C) Gradual recovery of the repaired facial; (D) Complete recovery. ***(Chapter 237)***

FIG. 15: Soft-tissue deficit of the upper lip following a human bite, which will require an expert plastic surgical repair. ***(Chapter 237)***

FIG. 16: Human bite on the nose with subtotal nasal loss which will require a complex plastic surgical repair. ***(Chapter 237)***

PLATE 50

FIGS. 17A TO C: (A) Pet dog bite with a through-and-through disruption of the upper and lower lips (front view); (B) Pet dog bite with a through-and-through disruption of the upper and lower lips (lateral view); (C) Results at postoperative day 30. ***(Chapter 237)***

FIGS. 18A AND B: (A) Table fan injury with devascularized left thumb, requiring neurovascular and tendon repair; (B) Postoperative month 3 results. ***(Chapter 237)***

FIGS. 2A AND B: (A) Partial thickness with partial thickness superficial burn noted on abdomen and bilateral thighs having partial-thickness superficial burns; (B) Flame burns: Upper extremity circumferential burns, causing a tourniquet effect on the distal forearm and hence predisposing to compartment syndrome. ***(Chapter 238)***

PLATE 51

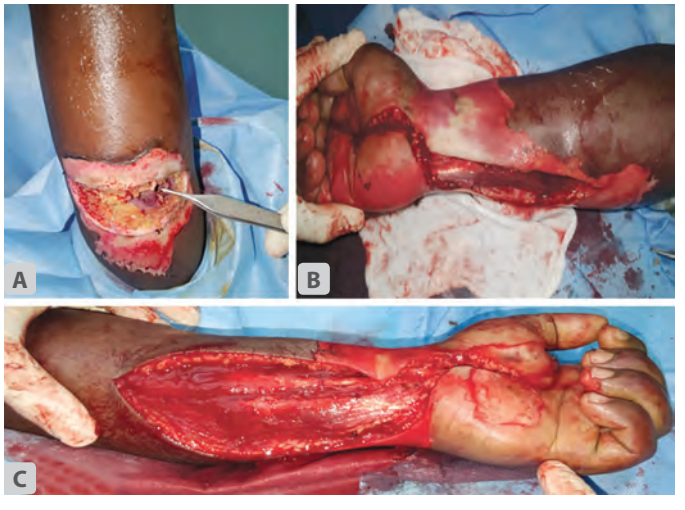
FIG. 4: Scalds due to accidental outpour of hot milk over the lower half of the face, chest, and abdomen. ***(Chapter 238)***

FIGS. 1A TO C: (A) "Flashover effect" over the posterior aspect of arm and forearm; (B) Superficial burns sustained after an electrical injury over lateral aspect of chest and abdomen; (C) Hyperpigmented skin with superficial burns. ***(Chapter 244)***

Courtesy: Dr Gaurav B Shetty.

FIGS. 2A TO C: Deep burns over posterior aspect of thigh and posterior gluteal region. ***(Chapter 244)***

Courtesy: Dr Gaurav B Shetty



FIGS. 4A TO C: S/p wound debridement of anterior aspect of forearm and posterior aspect of forearm. ***(Chapter 244)***

Courtesy: Dr Gaurav B Shetty.

FIG. 5: "Entry" site of an electrical burn, sustained from an electrical pole. ***(Chapter 244)***

Courtesy: Dr Gaurav B Shetty.

PLATE 52

FIG. 6: Checkerboard escharotomy done on a patient sustained more than 50% electrical burns. ***(Chapter 244)***

Courtesy: Dr Gaurav B Shetty.

FIGS. 2A AND B: (A) Common Indian cobra—*Naja naja*—head showing scales*;* (B) common Indian cobra—*Naja naja*—head showing hood and scales. ***(Chapter 245)***

Courtesy: Gerard Martin.

FIG. 1: Pit Viper showing pit between the nostril and eyes. ***(Chapter 245)***

FIG. 3: *Russell viper—Daboia russelii* head showing scales. ***(Chapter 245)***

Courtesy: Gerard Martin.

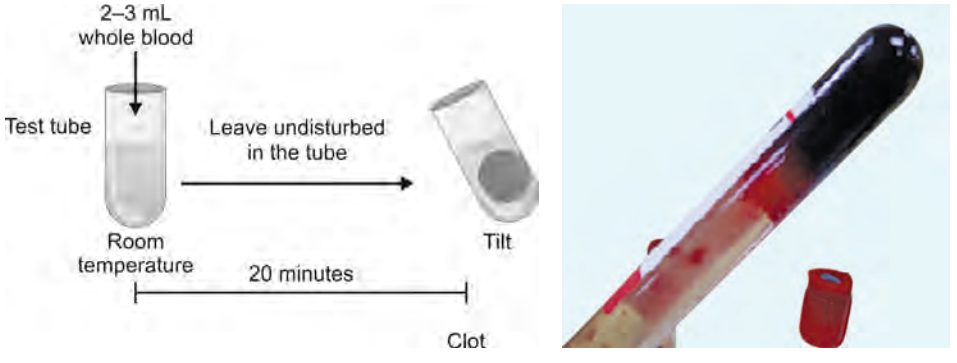


FIG. 5: Showing procedure of 20 whole blood clotting test (WBCT) to check coagulopathy in snake bite. ***(Chapter 245)***
